**Abstract.** A precise measurement of the inclusive deep-inelastic $e^+p$ scattering cross section is reported in the kinematic range $1.5 \leq Q^2 \leq 150\,\mathrm{GeV}^2$ and $3 \cdot 10^{-5} \leq x \leq 0.2$. The data were recorded with the H1 detector at HERA in 1996 and 1997, and correspond to an integrated luminosity of $20\,\mathrm{pb}^{-1}$. The double differential cross section, from which the proton structure function $F_2(x, Q^2)$ and the longitudinal structure function $F_L(x, Q^2)$ are extracted, is measured with typically 1% statistical and 3% systematic uncertainties. The measured derivative $(\partial F_2(x, Q^2)/\partial \ln Q^2)_x$ is observed to rise continuously towards small $x$ for fixed $Q^2$. The cross section data are combined with published H1 measurements at high $Q^2$ for a next-to-leading order DGLAP QCD analysis. The H1 data determine the gluon momentum distribution in the range $3 \cdot 10^{-4} \leq x \leq 0.1$ to within an experimental accuracy of about 3% for $Q^2 = 20\,\mathrm{GeV}^2$. A fit of the H1 measurements and the $\mu p$ data of the BCDMS collaboration allows the strong coupling constant $\alpha_s$ and the gluon distribution to be simultaneously determined. A value of $\alpha_s(M_Z^2) = 0.1150 \pm 0.0017(exp)^{+0.0009}_{-0.0005}\,(model)$ is

obtained in NLO, with an additional theoretical uncertainty of about $\pm 0.005$, mainly due to the uncertainty of the renormalisation scale.

## 1 Introduction

Deep-inelastic lepton-nucleon scattering (DIS) has been pivotal in the development of the understanding of strong interaction dynamics. Measurements of the inclusive DIS cross section have been essential for testing Quantum Chromodynamics (QCD) [1]. Previous fixed target DIS experiments have observed scaling violations, i.e. the variation of the structure functions with $Q^2$, the squared four-momentum transfer between lepton and nucleon, for fixed values of Bjorken-$x$, which are well described by perturbative QCD. The $Q^2$ evolution of the proton structure function $F_2(x, Q^2)$ is related to the gluon momentum distribution in the proton, $xg(x, Q^2)$, and to the strong interaction coupling constant, $\alpha_s$. These can be determined with precision deep-inelastic scattering cross section data measured over a wide range of Bjorken-$x$ and $Q^2$.

The first measurements of $F_2$ at low $x \sim 10^{-3}$ and $Q^2 \sim 20$ GeV$^2$ at HERA revealed a steep rise of $F_2(x, Q^2)$ towards low $x$ for fixed $Q^2$ [2,3]. Strong scaling violations are observed at low $x$ and are attributed to a high gluon density in the proton. The validity of the DGLAP evolution equations [4], which neglect higher-order terms [5, 6] proportional to $\alpha_s \cdot \ln(1/x)$, is questionable in the low $x$ range and therefore has to be tested against data. At extremely low $x$, non-linear gluon interaction effects have been considered in order to damp the rise of the cross section in accordance with unitarity requirements [7]. The study of quark-gluon interaction dynamics at high parton densities therefore continues to be a challenging subject. Knowledge of the parton densities at low $x$ is also necessary for interpreting measurements at hadron colliders and of cosmic neutrino interactions.

This paper presents new cross section measurements for the neutral current process $e^+p \to e^+X$ in the kinematic region $1.5 \le Q^2 \le 150\,\mathrm{GeV}^2$ and $3 \cdot 10^{-5} \le x \le 0.2$, obtained from data taken in the years 1996 and 1997 with positrons of energy $E_e = 27.6\,\mathrm{GeV}$ and protons of energy $E_p = 820\,\mathrm{GeV}$, corresponding to a centre of mass energy $\sqrt{s} = 300.9$ GeV. Cross section measurements at low $x$ and medium $Q^2$, based on the 1994 HERA data, were previously published by the H1 collaboration [8] and by the ZEUS collaboration [9]. The present measurement uses upgraded detectors to measure and identify the scattered positron, including new precision tracking for low $Q^2$ scattering. It also benefits from increased luminosity from HERA which enables an accuracy of typically 3% to be reached for the DIS cross section. Thus it considerably improves the former structure function measurements of the H1 collaboration [8,10,11] at $Q^2 \le 150\,\mathrm{GeV}^2$. The kinematic range is extended to larger $x$, yielding an overlap of H1 data with measurements from fixed target muon-proton scattering experiments for the first time. The paper includes a measurement of the derivative $(\partial F_2/\partial \ln Q^2)_x$, which serves as a sensitive test of the dynamics of strong interactions.

The longitudinal structure function $F_L(x, Q^2)$ is obtained with improved precision in an extended range of inelasticity $y$ and $Q^2$, as compared to its first determination at low $x$ [11]. A new method is introduced to extend the extraction of $F_L$ to $Q^2$ values below $10\,\mathrm{GeV}^2$ which uses the derivative $(\partial \sigma_r/\partial \ln y)_{Q^2}$ of the reduced cross section $\sigma_r$.

A next-to-leading order (NLO) DGLAP QCD analysis is performed using inclusive lepton-proton scattering data by introducing a new flavour decomposition of the structure function $F_2$. Hence it is independent of nuclear binding effects in the deuteron or heavier nuclei. The QCD analysis of the present low $x$ data and of the recently published high $Q^2$ H1 data [12] determines the gluon distribution $xg(x, Q^2)$ at low $x \ge 3 \cdot 10^{-4}$. The combination of the low $x$ H1 data with large $x$ data from the BCDMS experiment [13] enables an accurate, simultaneous determination of both $xg(x, Q^2)$ and $\alpha_s(M_Z^2)$. The present analyses use all of the available information regarding the experimental uncertainties of the data sets considered and explore the QCD model and fit parameter variations in a systematic way.

The paper is organised as follows. Section 2 defines the inclusive cross section and the methods used to reconstruct the event kinematics. The detector, the event selection and the simulation are described in Sect. 3. Section 4 presents the alignment and calibration methods, and summarises the cross section measurement. Section 5 presents the measurement of $(\partial \sigma_r/\partial \ln y)_{Q^2}$ and the determination of the longitudinal structure function $F_L$. The results for the proton structure function $F_2$ and its derivative $(\partial F_2/\partial \ln Q^2)_x$ are given in Sect. 6. The QCD interpretation of the data is discussed in Sect. 7, which refers to an appendix presenting details of the analysis. The paper is summarised in Sect. 8.

## 2 Cross section and kinematic reconstruction

The inclusive DIS cross section of the measured reaction $e^+p \to e^+X$ depends on two independent kinematic variables, chosen to be $x$ and $Q^2$, and on the centre of mass energy squared $s$, with the inelasticity variable $y = Q^2/sx$. In the one-photon exchange approximation the neutral current double differential cross section, $d^2\sigma/dxdQ^2$, is given by

$$\frac{d^2\sigma}{dxdQ^2} = \frac{2\pi\alpha^2 Y_+}{Q^4 x} \cdot \sigma_r \tag{1}$$

where the reduced cross section is defined as

$$\sigma_r \equiv F_2(x,Q^2) - \frac{y^2}{Y_+} \cdot F_L(x,Q^2) \tag{2}$$

and $Y_+ = 1 + (1-y)^2$. Due to the positivity of the cross sections for longitudinally and transversely polarised photons scattering off protons, the two proton structure functions $F_2$ and $F_L$ obey the relation $0 \le F_L \le F_2$. Thus the contribution of the longitudinal structure function $F_L$ to the cross section can be sizeable only at large values of the inelasticity $y$, and in most of the kinematic range the relation $\sigma_r \approx F_2$ holds to a very good approximation.

The HERA collider experiments allow DIS kinematics to be reconstructed using the scattered positron, the hadronic final state, or a combination of the two. This is important for maximum coverage of the kinematic range and the control of systematic uncertainties.

In the "electron method" the event kinematics are determined using the measured energy of the scattered positron $E'_e$ and its polar angle $\theta_e$ according to the relations

$$y_e = 1 - \frac{E'_e}{E_e}\,\sin^2(\theta_e/2), \quad Q^2_e = \frac{E'^2_e \sin^2\theta_e}{1-y_e}. \tag{3}$$

The coordinate system of H1 is defined such that the positive $z$ axis is in the direction of the incident proton beam. Polar angles $\theta$ are defined with respect to the proton beam direction. While the electron method is accurate at large $y$, corresponding to low $E'_e$, the resolution rapidly degrades with $1/y$ as $E'_e$ approaches the positron beam energy $E_e$.

The inelasticity $y$ can also be determined as [14]

$$y_h = \frac{\Sigma_i (E_i - p_{z,i})}{2E_e} \equiv \frac{\Sigma}{2E_e}, \tag{4}$$

where $E_i$ and $p_{z,i}$ are the energy and longitudinal momentum component of a particle $i$ in the hadronic final state, the masses being neglected. In this analysis the kinematics are also reconstructed with the "$\Sigma$ method" using the variables [15]

$$y_\Sigma = \frac{\Sigma}{\Sigma + E'_e(1-\cos\theta_e)}, \qquad Q^2_\Sigma = \frac{E'^2_e \sin^2\theta_e}{1-y_\Sigma}. \tag{5}$$

For all reconstruction methods, Bjorken-$x$ is calculated as $x = Q^2/sy$. Due to energy-momentum conservation the variable

$$E - p_z = \Sigma + E'_e(1-\cos\theta_e) \tag{6}$$

is approximately equal to $2E_e$. The hadronic variables $y_h$ and $y_\Sigma$ are related according to

$$y_\Sigma = \frac{y_h}{1 + y_h - y_e} \tag{7}$$

and can be well measured down to low $y \simeq 0.004$. The variable $y_\Sigma$ is less sensitive to initial state radiation than $y_h$ since the initial energy $E_e$ in the denominator in (4) can be calculated using the total energy reconstructed in the detector which leads to (5).

The hadronic scattering angle is defined as

$$\tan\frac{\theta_h}{2} = \frac{\Sigma}{P_{t,h}}, \tag{8}$$

where $P_{t,h}$ is the total transverse momentum of the hadronic final state particles. In the naive quark parton model, $\theta_h$ defines the direction of the struck quark related to $\theta_e$ as

$$\tan\frac{\theta_h}{2} = \frac{y}{1-y} \cdot \tan\frac{\theta_e}{2}. \tag{9}$$

For $y > 0.5$ the positron scattering angle $\theta_e$ is smaller than $\theta_h$. This relation, together with the definition of $y_e$ (3), determines the scattered positron energy from $\theta_e$ and $\theta_h$ in the "double angle method" [16].

## 3 Experimental procedure

### 3.1 H1 Detector

The H1 detector [17] combines tracking in a solenoidal magnetic field of 1.15 T with nearly hermetic calorimetry to investigate high-energy $ep$ interactions at HERA. The low $Q^2$ cross section measurement relies mainly on the central and backward tracking systems, the backward calorimeter (SPACAL) and the Liquid Argon (LAr) calorimeter. These components are briefly described below.

The energy of the positron, when scattered into the backward region of the H1 detector ($153^\circ < \theta_e < 177^\circ$), is measured in the SPACAL, a lead-fibre calorimeter [18, 19]. The SPACAL has an electromagnetic section with an energy resolution of $7\%/\sqrt{E/GeV} \oplus 1\%$, which together with a hadronic section represents a total of two interaction lengths. The SPACAL time resolution of less than 1 ns allows proton beam induced background to be vetoed. The calorimeter has a high transverse granularity which provides a determination of the transverse coordinates of electromagnetic clusters with an accuracy of a few millimeters and positron identification capability. Identification of the scattered positron is improved and the polar angle measured with a backward drift chamber (BDC), situated in front of the SPACAL, and a new backward silicon strip detector (BST) [20]. The BST consists of four detector planes, arranged perpendicularly to the beam axis which are equipped with 16 wedge shaped, double metal silicon strip detectors. The BST measures the polar angle of tracks with an internal resolution of about 0.2 mrad from radial coordinates between 5.9 cm and 12.0 cm.

The hadronic final state is reconstructed with the Liquid Argon calorimeter [21], the tracking detectors and the SPACAL. The LAr calorimeter is built of eight wheels of modules with an octant structure. The total depth of the calorimeter varies between 4 and 8.5 interaction lengths depending on the polar angle. In test beam measurements pion induced hadronic energies were reconstructed with a resolution of about $50\%/\sqrt{E/GeV} \oplus 2.0\%$ after software energy weighting [22].

The interaction vertex is determined with the central tracking detector consisting of two concentric jet drift chambers (CJC) and two concentric $z$ drift chambers (CIZ and COZ). The vertex determination is complemented by the inner proportional chamber CIP, for $167^\circ < \theta_e < 171^\circ$, and by the silicon tracker BST, for $171^\circ < \theta_e < 176.5^\circ$.

The luminosity is determined using the small-angle bremsstrahlung process $ep \rightarrow ep\,\gamma$. The final state photon and the positron, scattered at very low $Q^2$, can be detected in calorimeters ("electron and photon taggers") which are situated close to the beam pipe at distances of 33 m and 103 m from the interaction point in the positron beam direction. The luminosity is measured with a precision of 1.5% using the method outlined in [23].

### 3.2 Data samples and interaction triggers

The analysis comprises two different DIS event samples:

- Sample $A$ - data taken in the years 1996 and 1997 with luminosities of 4.5 pb$^{-1}$ and 13.4 pb$^{-1}$, respectively. These two data sets are combined to provide the cross section measurement for $Q^2$ values from 15 GeV$^2$ to 150 GeV$^2$ and for $Q^2 = 12$ GeV$^2$ at $y > 0.17$.
- Sample $B$ - data taken in the autumn of 1997 during a two week period dedicated to the lower $Q^2$ region. The data from this special run with a luminosity of 1.8 pb$^{-1}$ are used in the $Q^2$ range from 1.5 GeV$^2$ to 8.5 GeV$^2$ and for $Q^2$ =12 GeV$^2$ at low $y < 0.17$.

DIS events at low $Q^2$ are characterised by a positron scattered into the backward part of the H1 apparatus. The event trigger for sample $A$ requires local energy sums in the SPACAL calorimeter to be above an energy threshold of 6 GeV. This threshold is lowered to 5 GeV in sample $B$.

Both data samples are contaminated by photoproduction events in which the scattered positron escapes through the beam pipe and a particle in the hadronic final state mimics the signature of a scattered positron. For a fraction of these background events the scattered positron is detected in the electron tagging calorimeter. This background is significant only at low energies $E'_e$, corresponding to values of $y > 0.6$.

The region of high $y > 0.75$ is accessed with a dedicated trigger which requires a compact energy deposition (cluster) of more than 2 GeV of energy in the SPACAL, and a vertex signature in the proportional chamber system. The data accumulated with this trigger correspond to a luminosity of 2.8 pb$^{-1}$ in 1996 and 3.4 pb$^{-1}$ in 1997.

The SPACAL energy triggers are monitored with independent track triggers and found to be fully efficient for energies of about 1 GeV above threshold. The high $y$ trigger efficiency is determined to be 97% using independent calorimeter triggers. The online data reconstruction leads to a maximum loss of 0.5% of DIS events. This loss is estimated from monitor data and corrected for.

### 3.3 Event selection

The scattered positron is identified with the cluster of maximum transverse momentum $p_t$ in the SPACAL calorimeter, for which requirements on the cluster shape are satisfied. Electromagnetic energy deposition leads to clusters of smaller transverse extension than hadronic energy deposition. The transverse energy distribution of positron showers is determined experimentally using QED Compton events, and from radiative DIS events in which a photon is radiated from the incoming positron and detected in the photon tagger. The positron cluster radius [19,24] can thus be measured at all energies considered in the analysis, and a cluster radius cut of 4 cm is chosen. This cut removes a sizeable fraction of the photoproduction background while retaining more than 99% of the DIS signal.

A positron candidate cluster is required to be associated with a track segment in the BDC. The efficiency of the BDC is measured to be 98% on average with small radius dependent variations. A signal is also required in either the CIP or the BST where geometrically available. The efficiency of the CIP is about 98%. The track efficiency of the BST in the 1997 special run period is found to be about 93%. Efficiencies at low energies are determined using QED Compton scattering events and radiative DIS events.

Reconstruction of the interaction vertex is necessary to determine the event kinematics and to suppress beam background events. In the intermediate $y$ region, hadrons measured in the central tracking chambers allow vertex reconstruction with an efficiency exceeding 98%. However, at very low $y$ and also at very high $y$, where no hadron may be measured in the central tracking chambers, the vertex can be defined by the scattered positron if it falls within the acceptance of the CIP or the BST.

Longitudinal momentum conservation in neutral current DIS events gives the constraint that $E - p_z$, summed over the final state particles is about equal to $2E_e$ (6). In radiative events a photon may carry a significant fraction of the $E - p_z$ sum. Such events are thus suppressed by requiring $E - p_z > 35$ GeV.

The criteria applied to select DIS events are summarised in Table 1.

### 3.4 Simulation

For the calculation of the detector acceptance and efficiency control about $10^7$ inelastic events are simulated. Deep-inelastic events are generated using the DJANGO [25] event generator. This program is based on HERACLES [26] for the electroweak interaction and on the Lund Monte Carlo generator program ARIADNE [27], which

**Table 1.** Basic DIS event selection criteria. The radius of the cluster [19,24] defines the lateral shape of the energy deposition. The high $y$ region, corresponding to energies between $E'_e = 3\,\text{GeV}$ and $6.9\,\text{GeV}$, is accessed with additional cuts, as discussed in Sect. 4.3

| | |
|---|---|
| SPACAL energy | $> 6.9$ GeV |
| radius of cluster | $< 4$ cm |
| fraction of energy in the hadronic section | $< 15\%$ of $E'_e$ |
| cluster-BDC track distance | $< 1.5$ cm |
| cluster-BST track distance | $< 1.0$ cm |
| $z$ vertex position | $\|z\| < 30$ cm |
| $E - p_z$ | $> 35$ GeV |

includes the generation of diffractive events. This generator, when tuned to HERA data [28], presently gives the most reliable description of the final state properties [29]. To describe higher order QCD radiation processes the ARIADNE program uses the Colour Dipole Model (CDM) [30]. For hadron fragmentation the JETSET program is used [31]. Comparisons are done using the generator LEPTO [32]. QED Compton events are generated using the program COMPTON [33]. DIS events are also generated with the HERWIG event generator [34], which includes resonant final state production. This is important for the description of rejected events at very low $y$ [35]. Photoproduction background is generated with the PHOJET [36] program using the parameterisation of CKMT [37] to determine the virtual photon-proton interaction cross section. The normalisation of the PHOJET event sample is adjusted to the data measured with the electron tagging calorimeter. It is found to agree within 20% with the calculation of the cross section using the Weizsäcker-Williams approximation. Using the leading logarithmic approximation [38] the effect of photon radiation is estimated to be negligible.

The detector response is simulated in detail with a program based on GEANT3 [39]. The Monte Carlo events are subject to the same reconstruction and analysis chain as the real data. In the comparisons shown here, the simulated distributions are normalised to the measured luminosity. In the event generation the DIS cross section is calculated with the parton distributions of [40] and with the longitudinal structure function $F_L = 0$. A QCD fit to all the data is used to reweight the simulated cross section.

## 4 Measurement of the cross section

This section presents briefly the methods and results of the measurement of the deep-inelastic scattering cross section. Further details of the analysis are described in [24,35,41].

### 4.1 Detector alignment

The coordinate system of the H1 detector is defined by the central tracking chambers which determine the spatial coordinates of the interaction vertex. The variation of the vertex position in the $x, y$ plane along the beam direction is used to determine the inclination of the beam axis with respect to the $z$ axis.

The central tracking chambers are aligned with respect to each other using cosmic muon tracks. The alignment of the BDC and of the SPACAL with respect to the central tracker is done by studying the difference of the polar angles measured by these detectors as a function of the azimuthal angle. This results in 1 to 2 mm adjustments of the nominal detector positions. QED Compton events, which have the signature of back-to-back positron and photon clusters, provide a cross check for the alignment [24] of the SPACAL in the transverse plane to an accuracy of 0.2 mm. After internal adjustment of the strip detector planes, the spatial position of the BST is determined using the event vertex $z$ coordinate measured with the central tracker.

In the BST angular acceptance range the polar angle is measured both by the BDC using the interaction vertex, and by the BST track segment. This allows the alignment procedure to be checked to within an accuracy of $\Delta\theta$ of 0.1 mrad [35]. From the residual dependence of $\Delta\theta$ on the azimuthal angle and from the uncertainties of the alignment procedure, a measurement error of 0.3 mrad is estimated for the angle of the scattered positron.

### 4.2 Calibration of the energy measurements

The energy of the scattered positron is measured in the SPACAL, which has a transverse cell size of $4 \times 4\ \text{cm}^2$ and a Molière radius of 2.5 cm. In a first step the responses of the SPACAL cells are equalised using cosmic muons. The energy scale of each cell is determined with DIS events using the double angle method, which allows the energy of the scattered positron to be expressed as a function of $\theta_e$ and $\theta_h$. This method is applied to the data of the various run periods, and also to the simulated events. Agreement of the energy scales is found at the level of 0.2%. The calibration procedure leads to a systematic error of the $E'_e$ scale of 0.3% for most of the SPACAL area and energies $E'_e$ above 20 GeV. The energy calibration at lower energies is performed using QED Compton events. This leads to an estimated maximum energy scale uncertainty of 2.7% at 3 GeV. This uncertainty is observed to approach linearly the 0.3% level at maximum energies $E'_e \simeq E_e$. The SPACAL response at the lowest energies is cross checked by studying the $\pi^0$ mass reconstructed from pairs of photons in the energy range of $0.8 - 4\,\text{GeV}$ [24,42]. Material in front of the calorimeter leads to showering and energy losses, which are corrected for using the backward drift chamber as a preshower detector [43]. Figures 1a,b and 2a,b show the energy and polar angle distributions for data samples $A$ and $B$. These are described by the simulation of DIS and photoproduction events.

The cross section measurement at low $y$ relies on the measurement of $y$ using the hadronic final state (4). The determination of $y$ is optimised by combining calorimeter energy deposits with low momentum tracks. The sum over energy clusters in the calorimeters can be strongly affected by electronic noise, in particular for low $y < 0.03$.

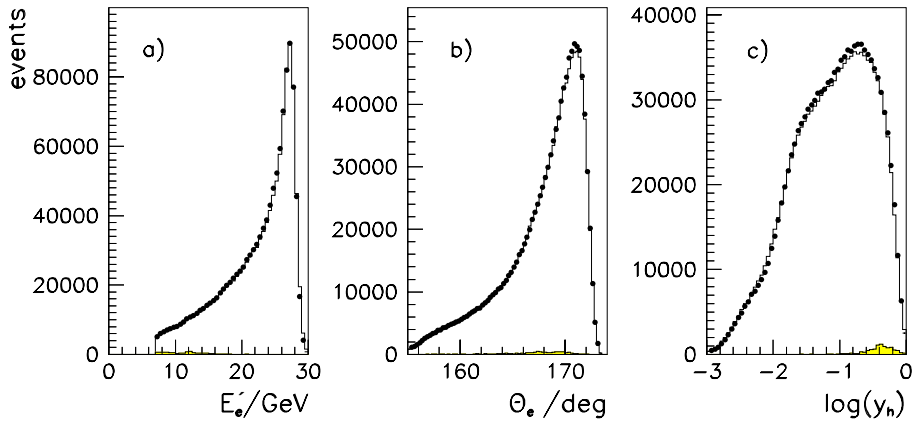

**Fig. 1a–c.** Distributions of **a** the energy, **b** the polar angle of the scattered positron, and **c** $y_h$ for the data sample $A$ taken in 1996/97 (solid points). The histograms show the simulation of DIS and the small photoproduction background (shaded), normalised to the luminosity of the data

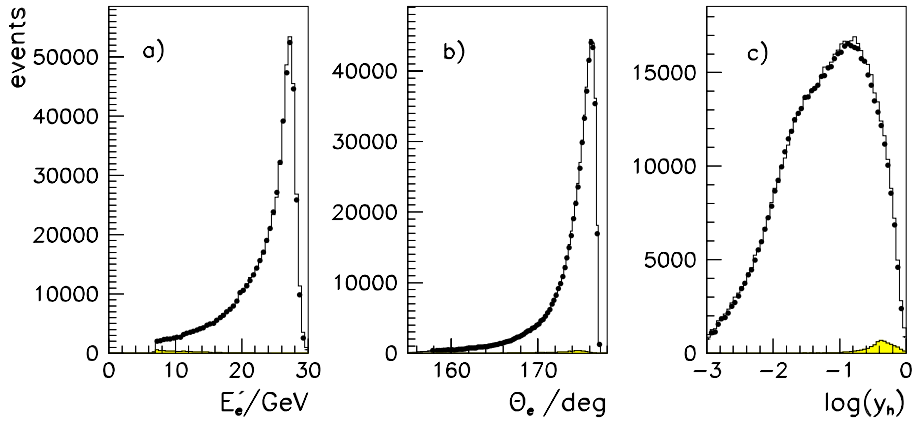

**Fig. 2a–c.** Distributions of **a** the energy, **b** the polar angle of the scattered positron, and **c** $y_h$ for the low $Q^2$ data sample $B$ taken in 1997. The histograms represent the simulation of DIS and the small photoproduction background (shaded), normalised to the luminosity of the data

Thus an additional noise suppression is performed which excludes isolated depositions of energy less than 400 MeV (800 MeV) in the central (forward) region of the LAr calorimeter from the analysis of both data and simulated events. This leads to a small signal loss but improves the $y$ resolution at low $y$. The uncertainty of this subtraction procedure is estimated to correspond to a quarter of the suppressed noise contribution to the reconstructed hadron energy.

The calibration of the hadronic energy measurement uses the $p_t$ balance between the scattered positron and the hadronic final state. The energy scales for the electromagnetic and hadronic sections of wheels and octants [35] of the LAr calorimeter result from a Lagrangian multiplier technique which simultaneously determines all 128 calibration constants. A systematic uncertainty of 2% on the hadronic energy scale in the LAr calorimeter is determined, based on a binwise comparison of different calibration methods. The results of the energy calibration procedure are consistent with those recently presented [12].

Figures 1c and 2c show the experimental $y_h$ distributions over three orders of magnitude in $y$. In the simulation, the $y_h$ reconstruction is found to be accurate to within a few% over a wide range of $y_h$ and down to the small $Q^2$ region. The worse $y$ resolution at low $y$ is accounted for with an increased bin size, allowing the $y$ range to be extended down to $y \simeq 0.004$.

The response of the SPACAL to hadronic energy flow is calibrated using longitudinal momentum conservation in the DIS events [24] to within an uncertainty of 5%. This scale uncertainty affects the final cross section data at large $y$ through the $E - p_z$ momentum balance requirement.

### 4.3 Measurement at large $y$

For the measurement of the longitudinal structure function it is essential to reach the maximum possible values of $y$ (see (2)). This requires an efficient rejection of photoproduction background events in which low energy deposits in the SPACAL can mimic the signature of a deep-inelastically scattered positron.

At $Q^2$ below 10 GeV$^2$, the range $y \leq 0.75$ is accessed by requiring a track signal in the BST. This requirement removes a sizeable fraction of the background where a cluster in the SPACAL is due to photons from $\pi^0 \to \gamma\gamma$ decays. The remaining background is due to photon conversion and showering in the passive material, possible overlap of $\pi^0$ decays with charged tracks, and misidentified charged pions. This background is subtracted bin by bin using the PHOJET event simulation. Figures 3a and 3b illustrate the range of polar angle and energy for high $y$ events with a track in the BST. The photoproduction background can be estimated experimentally using a data sample of events which have a positron detected in the

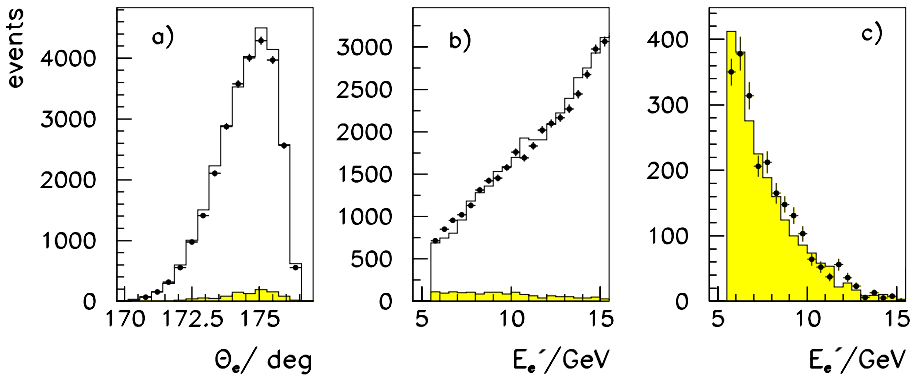

**Fig. 3a–c.** Distributions illustrating the cross-section measurement at high $y$ ($0.46 < y < 0.82$) and low $Q^2$ ($2 < Q^2 < 5$ GeV$^2$) for events in the BST acceptance range. DIS event distributions of **a** the polar angle and **b** the SPACAL energy of the scattered positron candidate. **c** SPACAL energy distribution for tagged photoproduction events fulfilling the DIS event selection criteria, apart from the $E - p_z$ requirement. Solid points: H1 data; shaded histograms: simulation of photoproduction events; open histograms: added distributions of simulated DIS and photoproduction events

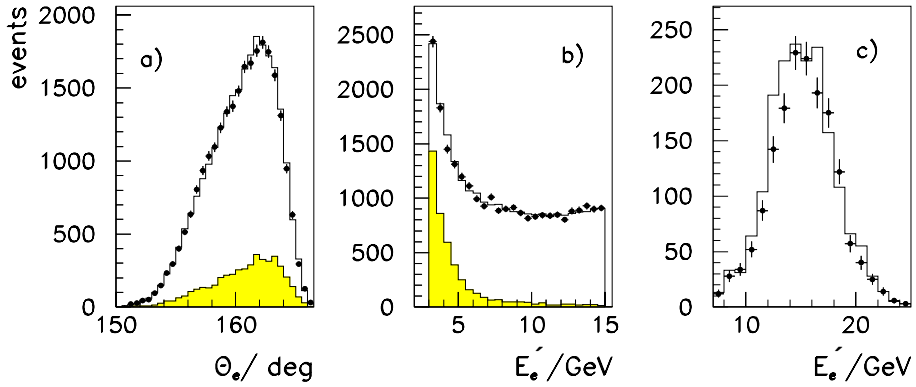

**Fig. 4a–c.** Distributions illustrating the cross-section measurement at high $y$ ($0.46 < y < 0.89$) and large $Q^2$ ($10 < Q^2 < 35$ GeV$^2$). **a** Polar angle and **b** SPACAL energy distributions before subtraction of the photoproduction background using the charge measurement by the CJC. Solid points: data with positive charge assignment. Shaded histogram: data with negative charge assignment. Open histogram: sum of data with negative charge assignment and DIS event simulation, normalised to the data luminosity. **c** Spectrum of energy measured in the electron tagger for DIS candidate events with a linked track of either positive charge (solid points) or of negative charge (histogram)

electron tagger. Figure 3c shows the energy spectrum of SPACAL clusters for those events which satisfy the DIS selection criteria, apart from the $E-p_z$ requirement. This distribution is well described by the simulation.

At $Q^2$ above 10 GeV$^2$, for $y < 0.75$, the photoproduction background is subtracted using the PHOJET event simulation. For $y$ above 0.75, however, experimental information is used by employing the charge assignment of central tracks associated with SPACAL energy clusters. This allows the energy range to be extended down to $E'_e = 3$ GeV, corresponding to $y \leq 0.89$. For $12 \leq Q^2 \leq 35$ GeV$^2$ tracks reconstructed in the CJC can be linked to low energy SPACAL clusters with an efficiency of 95% (93)% in 1996 (1997). For such tracks with energies up to 15 GeV the charge is determined with an efficiency of 99.5% [24]. The sample of candidates with negative charge is taken to represent the background in the positron data sample.

The statistical subtraction procedure requires the study of any process which may cause a charge asymmetry. This asymmetry can be measured using tagged photoproduction events which fulfill the DIS event selection criteria. A small charge asymmetry $(N_+ - N_-)/(N_+ + N_-)$ is found with an average of $-4.8\%$ with a statistical accuracy of 1.9%, for $0.65 < y < 0.89$. Here $N_+(N_-)$ is the number of events with positive (negative) charge of the track associated with the SPACAL cluster. Comparing the energy distribution for a sample of negative tracks in $e^+p$ scattering, taken in 1996/1997, with that for a sample of positive tracks in $e^-p$ scattering, taken in 1999, a consistent asymmetry of $(-3.5\pm2.5)\%$ is measured. Background simulation studies and measurements of the ionisation losses in the CJC reveal that this small asymmetry is due to the antiproton interaction cross section exceeding that for proton interactions at low energies [44]. Annihilation leads to larger energy deposits in SPACAL than proton interactions which introduces an asymmetry for low energies above a given threshold. This charge asymmetry is taken into account in the measurement of the positron DIS cross section at high $y$. Selected control distributions [24, 41] are shown in Fig. 4 illustrating the good understanding of this

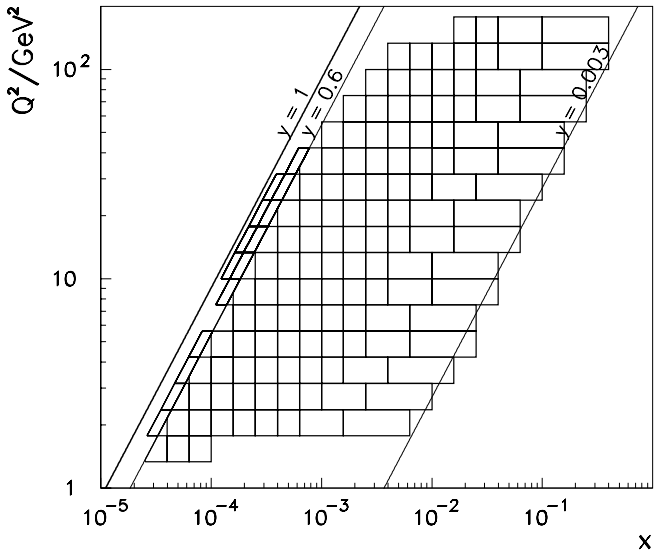

**Fig. 5.** Division of the $(x, Q^2)$ plane for the measurement of the inclusive DIS cross section. At low $y$ the bin size increases as the resolution deteriorates. At large $y$ the data are binned in intervals of $Q^2$ and $y$ in order to account for the $y$ dependent effect of $F_L$ on the cross-section and the variation of the systematics with $y$. The triangular regions inside the acceptance do not represent valid analysis bins

kinematic region down to scattered positron energies of $E'_e = 3\,\mathrm{GeV}$.

### 4.4 Results

An iterative bin wise correction procedure is adopted for the extraction of the double differential cross section $\sigma_r$. This procedure requires that the bin sizes are adapted to the resolution in the measurement of the kinematic variables. The data and the simulated events are binned in a grid in $x$ with five bins per decade and in $Q^2$ with eight bins per decade, as illustrated in Fig. 5. At low $y$ the resolution of the measurement degrades and the bin size is widened. For $y > 0.6$ the data are divided in bins of $y$, and the $Q^2$ division is kept. In this region the cross section may receive a large negative contribution from $F_L$ proportional to $y^2$ and therefore a fine binning in $y$ is desirable. Bins are accepted if the purity and stability are bigger than 30% with typical values being 60%. Here the purity (stability) is defined as the number of simulated events which originate from a bin and which are reconstructed in it, divided by the number of reconstructed (generated) events in that bin.

The longitudinal momentum conservation constraint, $E - p_z > 35\,\mathrm{GeV}$, limits the amount of radiative corrections to at most 5% at high $y$. The program HERACLES [26], which is used in the DIS event simulation, accounts for first order radiative corrections to the one photon exchange approximation. The radiative corrections are extracted using a high statistics calculation within the HERACLES Monte Carlo program, and compared with the results of the numerical program HECTOR [45], which includes higher order and hadronic corrections. The corrections are found to agree within the statistical accuracy of the radiative event simulation of 0.5%.

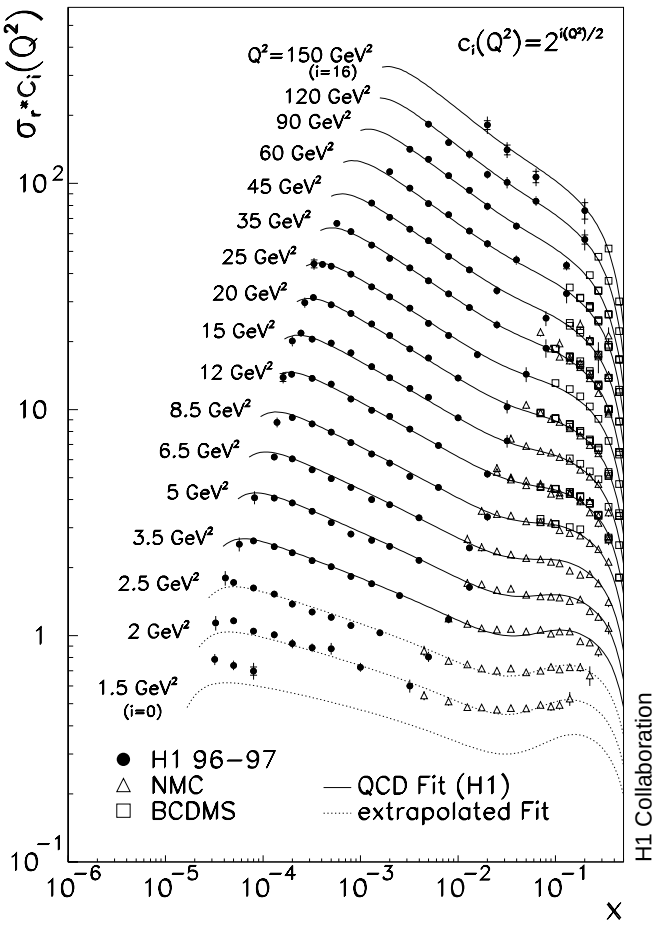

**Fig. 6.** Measurement of the reduced DIS scattering cross section (closed points). Triangles (squares) represent data from the NMC (BCDMS) muon-proton scattering experiments. The solid curves illustrate the cross section obtained in a NLO DGLAP QCD fit to the present data at low $x$, with $Q^2_{min} = 3.5\ \mathrm{GeV}^2$, and to the H1 data at high $Q^2$. The dashed curves show the extrapolation of this fit towards lower $Q^2$. The curves are labelled with the $Q^2$ value the data points belong to and scale factors are conveniently chosen to separate the measurements

The results of the measurement are summarised in Tables 9-12. At $y > 0.17$ the kinematics are reconstructed using the quantities $Q^2_e$ and $y_e$. At $y < 0.17$, where the resolution of $y_e$ degrades, the variables $Q^2_\Sigma$ and $y_\Sigma$ are used. The error calculation for the measurement is discussed below. The full error correlation matrix can be obtained from the H1 Collaboration [46].

The cross section measurement is shown in Fig. 6 as a function of $x$ for different $Q^2$. Due to the extension of the measurement towards low $y$, the H1 data overlap with data of fixed target $\mu p$ experiments. The H1 measurement agrees well with the fixed target data within the uncertainty of about 7%. The cross section rises towards low $x$. This rise is observed to be damped at the smallest values

**Table 2.** Sources and sizes of normalisation errors

| source | cross section error [%] |
|---|---|
| online event selection | 0.5 |
| BDC efficiency | 0.5 |
| trigger efficiency | 0.5 |
| luminosity measurement | 1.5 |

**Table 3.** Sources of correlated systematic errors and their typical effect on the cross section measurement accuracy

| source | size of uncertainty | typical cross section error [%] |
|---|---|---|
| scattered positron energy scale | 0.3% at $E'_e \simeq 27.5\,\mathrm{GeV}$ | 1 |
| | 2.7% at $E'_e = 3\,\mathrm{GeV}$ | 2 |
| scattered positron angle | 0.3 mrad | 0.5 |
| hadronic energy scale in LAr | 2% | 2 |
| LAr noise | 25% of noise | max of 5 at lowest $y$ |
| photoproduction background | 20% of background | 3 at large $y$ |

of $x$, which is attributed to the longitudinal structure function, see Sect. 5. The cross section can be well described by a QCD fit to the data as discussed in Sect. 7.

### 4.5 Systematic errors

The statistics of the data presented here exceed $10^4$ events in most of the bins. The precision for this measurement is dominated by systematic uncertainties of typically 3%. These are classified into a global normalisation uncertainty, kinematically correlated errors ($\delta_{cor}$), the statistical errors of the data ($\delta_{sta}$) and uncorrelated errors ($\delta_{unc}$). The uncorrelated errors contain the statistical uncertainty of the simulation and further errors due to local systematic effects.

Table 2 lists those errors which result in a possible global change of all data points. The resulting total normalisation uncertainty of the data is 1.7%. It is dominated by the error on the luminosity measurement.

Energy calibration and alignment uncertainties cause systematic errors which depend on the kinematics and introduce correlations between the measured data points. These errors are determined using the simulation program and verified by an analytic calculation. They are found to be symmetric to good approximation. The uncertainty of the photoproduction background simulation is estimated to be 20%. The correlated error sources are listed in Table 3.

As a cross check of the positron identification, the scattered positron is also considered to be the cluster of maximum energy. When this alternative positron identification criterion is used, the cross section changes by less than 1%. This is accounted for in the systematic error. Detailed studies using different event generators with differing simulations of the hadronic final state verify the reliability of the positron identification procedure within the quoted systematic uncertainty [24].

**Table 4.** Additional sources of systematic errors and effect on the cross section for the analysis, in the range $12 < Q^2 < 25\,\mathrm{GeV}^2$, in which central jet chamber tracks are used to measure the charge of the positron candidate

| source | error of cross section [%] |
|---|---|
| positron identification | 1 |
| track charge determination | 0.5 |
| charge asymmetry | 1 |
| CJC-SPACAL track link efficiency | 2 |
| hadronic track requirement in CJC | 1 |
| high $y$ trigger efficiency | 1 |
| radiative corrections | 1 |

Uncertainties due to radiative corrections, positron identification and final state simulation details are treated as uncorrelated systematic errors. The errors introduced by the track based background subtraction procedure in the high $y$ data analysis (Sect. 4.3) are summarised in Table 4.

For each kinematic bin the resulting cross section errors are given in the cross section Tables 9-12.

## 5 Longitudinal structure function $F_L(x, Q^2)$

The extraction of the longitudinal structure function is based on the reduced double differential cross section (2), which depends on two proton structure functions, $F_2(x, Q^2)$ and $F_L(x, Q^2)$. The contribution of $F_L$ is enhanced with $y^2$, and the reduced cross section $\sigma_r$ tends to $F_2 - F_L$ for $y \to 1$. In the quark-parton model, the longitudinal structure function is zero for spin 1/2 quarks [47]. In QCD, parton radiation processes [48] lead to non-zero values of $F_L$. Thus $F_L$ contains information about the gluon distribution and about the strong interaction dynamics which is complementary to that obtained from the analysis of the scaling violations in $F_2(x, Q^2)$. At low $Q^2$ the longitudinal structure function is expected to be particularly sensitive to higher-order corrections to DGLAP QCD [49–51].

The longitudinal structure function can be extracted from the inclusive cross section only in the region of large $y$. An important advantage of HERA, compared to fixed target DIS lepton-nucleon experiments, is the wide range of $y$ values covered. This allows the behaviour of $F_2$ at low $y$ to be determined reliably and to be extrapolated into the region of high $y$. Two methods are used here to perform an extraction of the longitudinal structure function. For larger $Q^2$, a NLO DGLAP QCD fit is used to extrapolate $F_2$ into the high $y$ region, and $F_L$ is obtained with the "extrapolation method" introduced previously [11]. This fit uses only H1 data in the restricted kinematic range $y < 0.35$ and $Q^2 \geq 3.5$ GeV$^2$. Details of this and other

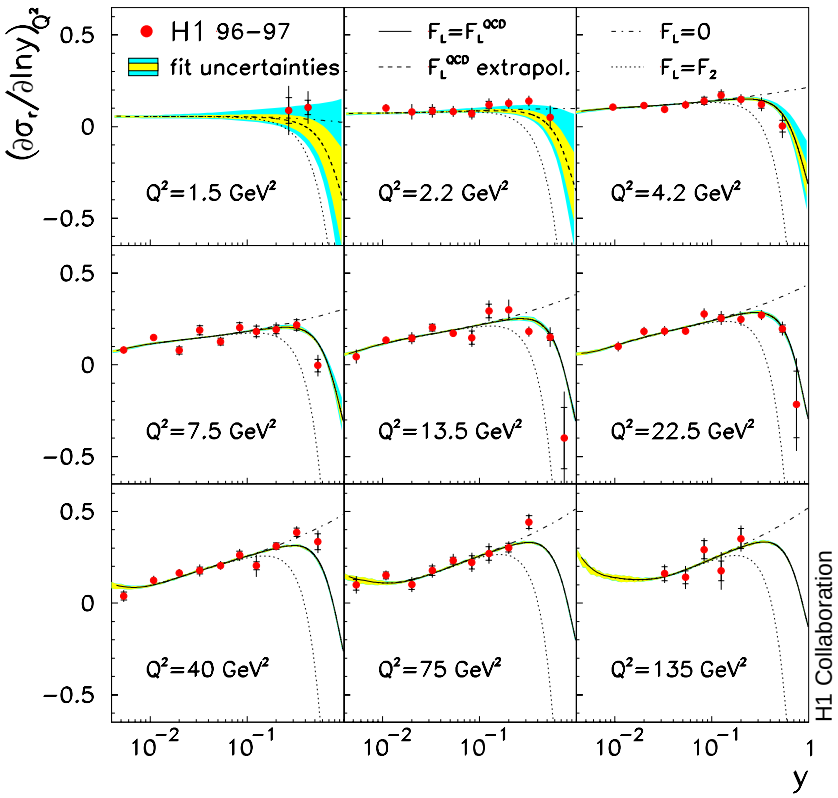

**Fig. 7.** Measurement of the derivative $\partial\sigma_r/\partial\ln y$ at fixed $Q^2$. The inner error bars represent the statistical errors and the total error bars the statistical and systematic errors, added in quadrature. The curves represent the QCD fit result to the H1 data, for $y < 0.35$ and $Q^2 \geq 3.5\,\mathrm{GeV}^2$, calculated with different assumptions about $F_L$. The solid curves use the QCD prediction of $F_L$, the dashed (dashed dotted) curves assume $F_L = F_2$ ($F_L = 0$). The inner error band is the experimental uncertainty of the fit result (Sect. 7.2), the outer band represents the additional uncertainty due to the fit assumptions. The fit results shown for $Q^2 < 3.5$ GeV$^2$ (dashed) are obtained by backward extrapolation

QCD fits to H1 and fixed target data are presented in Sect. 7. At low $Q^2 < 10\,\mathrm{GeV}^2$, the behaviour of $F_2$ as a function of $\ln y$ is used in a new extraction method [41], termed the "derivative method" as it is based on the cross section derivative $(\partial\sigma_r/\partial\ln y)_{Q^2}$.

### 5.1 Cross section derivative $(\partial\sigma_r/\partial\ln y)_{Q^2}$

The derivative of the reduced cross section, taken at fixed $Q^2$, is given by

$$\left(\frac{\partial\sigma_r}{\partial\ln y}\right)_{Q^2} = \left(\frac{\partial F_2}{\partial\ln y}\right)_{Q^2} - F_L\cdot 2y^2\cdot\frac{2-y}{Y_+^2} - \frac{\partial F_L}{\partial\ln y}\cdot\frac{y^2}{Y_+} \qquad (10)$$

For $y \to 1$ the cross section derivative tends to the limit $(\partial F_2/\partial\ln y)_{Q^2} - 2\cdot F_L$, neglecting the contribution from the derivative of $F_L$. At largest $y$ the $F_L$ contribution dominates the derivative of the reduced cross section $\sigma_r$. This is in contrast to the influence of $F_L$ on $\sigma_r$ which is dominated by the contribution of $F_2$ for all $y$. A further advantage of the derivative method is that it can be applied down to very low $Q^2 \simeq 1\,\mathrm{GeV}^2$ where a QCD description of $F_2(x,Q^2)$ is complicated due to higher order and possible non-perturbative corrections.

To obtain an accurate determination of $(\partial\sigma_r/\partial\ln y)_{Q^2}$ the data are rebinned in $Q^2$ by combining data of two adjacent $Q^2$ intervals. Differences $\Delta\sigma_r$ are calculated between cross section points adjacent in $y$ at fixed $Q^2$. A bin-centre correction is applied to obtain the derivative at each $y$ point, which is chosen to be the average of the two $y$ values of the cross section measurements used to calculate the derivative. A full error analysis is performed in order to account for the correlations of errors, which partially cancel. The two adjacent data points of the derivative are anti-correlated since they use the same cross section measurement with different sign. The cross section derivatives are shown in Fig. 7, and the values are given in Tables 13 and 14. The measured derivatives are well described by the QCD calculation (Sect. 7.2).

For low $Q^2$ and $y < 0.3$ the derivative is observed to be a linear function of $\ln y$. The structure function $F_2(x,Q^2)$, at fixed $Q^2$, behaves like $x^{-\lambda} \propto y^{\lambda}$. At low $Q^2$ the exponent $\lambda$ is observed to be small and the derivative is thus expected to be approximately linear in $\ln y$. This approximation is used to determine the longitudinal structure function at low $Q^2$. For larger $Q^2$ the exponent $\lambda$ rises and a curvature is expected as can be seen in Fig. 7.

### 5.2 Determination of $F_L$

For the determination of $F_L$ for $Q^2 < 10\,\mathrm{GeV}^2$ straight line fits are performed in $\ln y$ to the derivative $(\partial\sigma_r/\partial\ln y)_{Q^2}$ for $y \leq 0.2$. These straight lines describe the data well (Fig. 7) and are extrapolated to estimate the contribution of $\partial F_2/\partial\ln y$ at high $y$. The uncertainty on this extrapolation is included in the systematic errors of the $F_L$ determination, taking into account the correlations of errors at low $y$ with those at high $y$. The extrapolations are compared with the values obtained from the QCD analysis

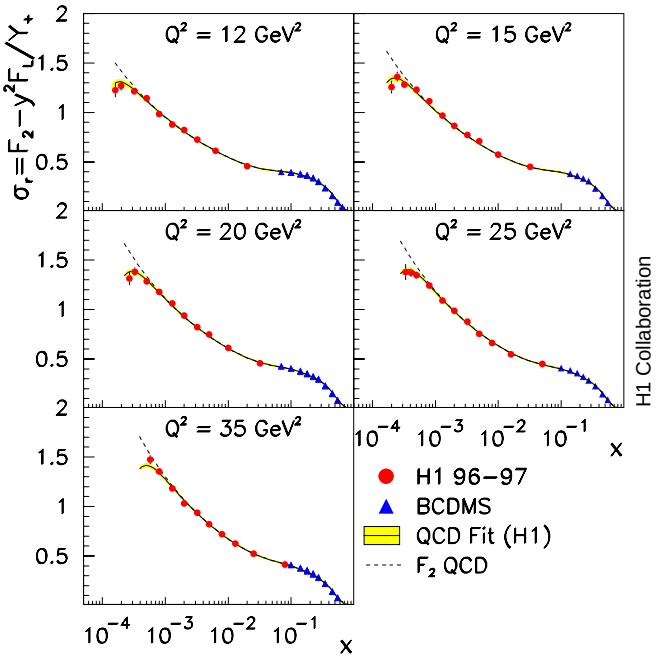

**Fig. 8.** Measurement of the reduced DIS scattering cross section (closed points). Triangles represent data from the BCDMS muon-proton scattering experiment. The curves represent a NLO QCD fit to the H1 data alone, using data with $y < 0.35$ and $Q^2 \geq 3.5$ GeV$^2$. The dashed curves show the $F_2$ structure function as determined with this fit. The error bands represent the experimental and model uncertainty of the QCD fit

and very good agreement has been found. The contribution of $\partial F_L / \partial \ln y$ to the derivative (10) is neglected. The uncertainty of this approximation is estimated using the derivative of $F_L$ as calculated in QCD. It is taken as an additional uncertainty on the measurement, and amounts to about a quarter of the systematic uncertainty of $F_L$.

For $Q^2 > 10\,\mathrm{GeV}^2$, the NLO QCD fit of the H1 data for $y < 0.35$ is used to estimate $F_2$ in the high $y$ (i.e. small $x$) region. In this $Q^2$ range, the extrapolation method is more accurate than the derivative method. The derivative method is statistically limited at maximum $y$ since this region is accessed only with a combined SPACAL and track trigger. Figure 8 compares the fit with the measured cross section for those five $Q^2$ bins above 10 GeV$^2$ which access the high $y$ region. The difference between the measured $\sigma_r$ and the extrapolated $F_2$ is used to determine $F_L(x, Q^2)$ as described in [11]. Systematic errors, which are common to the lower $y$ and the large $y$ region, are considered in the fit as described in [52].

The $F_L$ values obtained are presented in Table 15. The uncertainties on the longitudinal structure function include several sources: the statistical errors, uncorrelated systematic errors and correlated systematic errors, resulting e.g. from the $y$ dependent amount of subtracted photoproduction background. In addition, errors are associated with the assumptions inherent to the extraction methods. For the derivative method these errors are dominated by the uncertainty of the straight line fit, and for the extrapolation method by the variation of the smallest $Q^2$ of data used in the QCD fit, see Sect. 7.2. As can be seen in Table 15, these errors are smaller than the experimental systematic errors. In the region of overlap, for $Q^2$ between 4 GeV$^2$ and 15 GeV$^2$, the derivative method and the extrapolation method give consistent results. Further details of this analysis are described in [41].

The values for $F_L(x, Q^2)$, given in Table 15, are consistent with the previous determination of $F_L$ by the H1 collaboration [11], but they are more precise and obtained in a wider kinematic range. The H1 data extend the knowledge of the longitudinal structure function beyond that obtained from fixed target lepton-proton scattering experiments into the region of much lower $x$, see Fig. 9. The increase of $F_L(x, Q^2)$ towards low $x$ is consistent with the NLO QCD calculation (Sect. 7.2), reflecting the rise of the gluon momentum distribution towards low $x$. The values of $F_L(x, Q^2)$ are thus severely constrained unless there are deviations from the assumed extrapolation of $F_2$ into the region of large $y$ corresponding to the smallest $x$. A measurement of the $x$ dependence of $F_L(x, Q^2)$ can be performed independently of assumptions about the behaviour of $F_2$ with a variation of the proton beam energy at HERA [53].

## 6 Structure function $F_2$ and derivative $(\partial F_2 / \partial \ln Q^2)_x$

The proton structure function $F_2(x, Q^2)$ is obtained from the measured reduced cross section using (2) rewritten as

$$F_2 = \sigma_r \cdot \left(1 - \frac{y^2}{Y_+} \cdot \frac{R}{1+R}\right)^{-1}. \qquad (11)$$

The ratio $R = F_L/(F_2 - F_L)$ is determined using the standard DGLAP QCD fit to the H1 data (Sect. 7.2), calculating $F_L$ to order $\alpha_s^2$. In order to reduce the dependence of the measurement on $F_L$, the $F_2$ extraction is limited to the range $y \leq 0.6$. The results for $F_2(x, Q^2)$ and the calculated values of $F_L(x, Q^2)$ are given in Tables 9-12. This measurement is consistent with, and improves upon, the previous results [8], which were obtained with a different backward apparatus.

In Fig. 10 the measurement of the structure function $F_2(x, Q^2)$ at low $x$ is shown as a function of $Q^2$. The data are well described by the NLO QCD fit, as is discussed in detail in Sect. 7.2. The ln $Q^2$ dependence of $F_2$ is observed to be non-linear. It can be well described by a quadratic expression

$$P_2(x, Q^2) = a(x) + b(x) \ln Q^2 + c(x)(\ln Q^2)^2, \qquad (12)$$

which nearly coincides with the QCD fit in the kinematic range of this measurement.

The DGLAP evolution equations are governed by the derivative $(\partial F_2 / \partial \ln Q^2)_x$ taken at fixed $x$. Measurement of this derivative has long been recognised as a powerful constraint on $xg$ and $\alpha_s$ [54]. In the low $x$ DIS region its behaviour is a direct reflection of the behaviour of the gluon density [55]. This quantity has also been studied

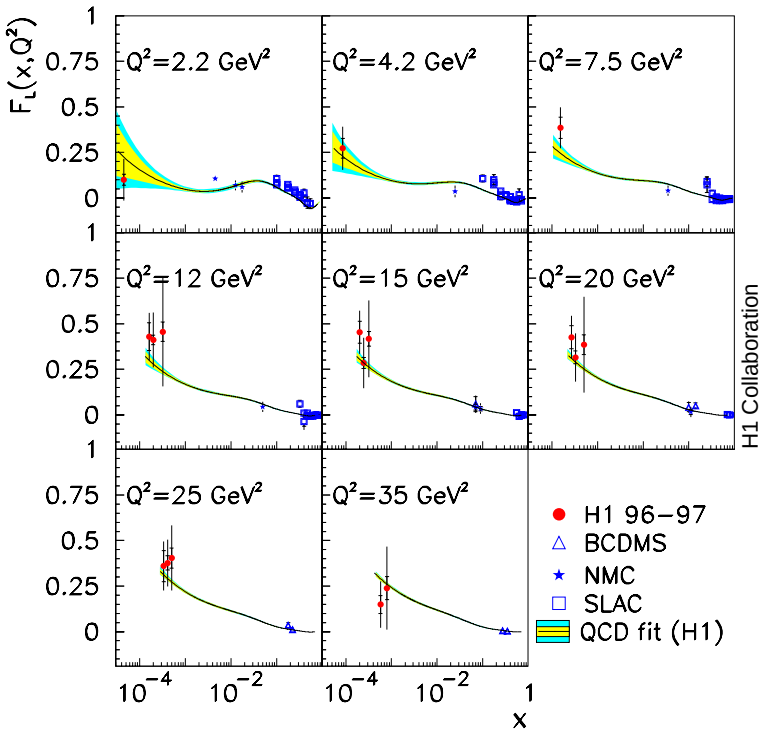

**Fig. 9.** The longitudinal structure function $F_L(x, Q^2)$ for different bins of $Q^2$ as obtained by H1 at low $x$, and by charged lepton-nucleon fixed target experiments at large $x$. The measurements for $Q^2 < 10$ GeV$^2$ are determined with the derivative method while the points for larger $Q^2$ are due to the extrapolation method. The error on the data points is the total uncertainty of the determination of $F_L$ representing the statistical, the systematic and the model errors added in quadrature. The inner error bars show the statistical error. The error bands are due to the experimental (inner) and model (outer) uncertainty of the calculation of $F_L$ using the NLO QCD fit to the H1 data for $y < 0.35$ and $Q^2 \geq 3.5\,\mathrm{GeV}^2$

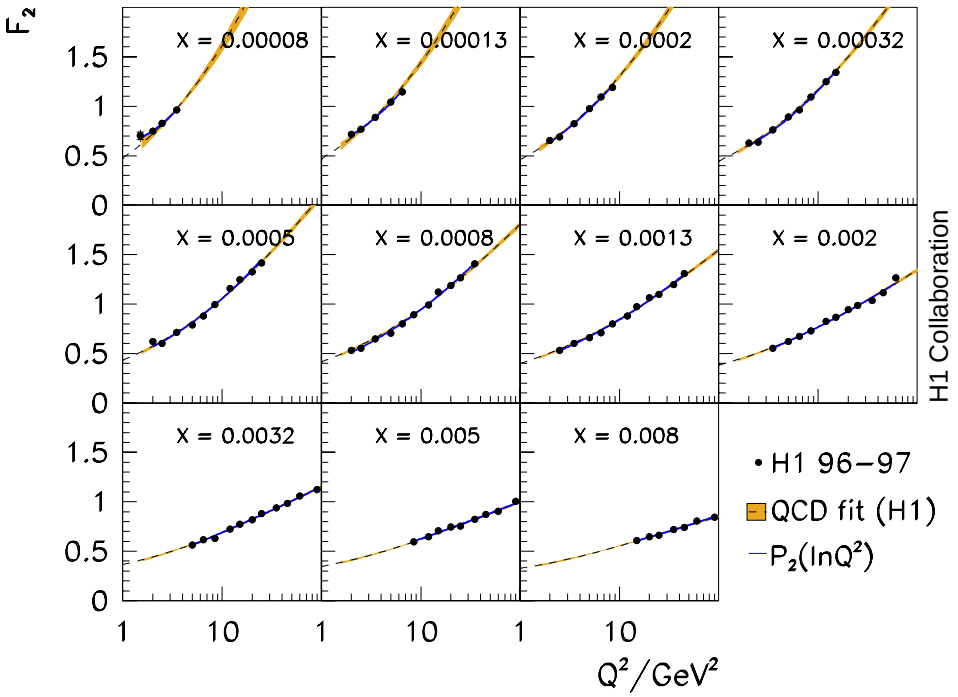

**Fig. 10.** Measurement of the proton structure function $F_2(x, Q^2)$, plotted as functions of $Q^2$ in bins of $x$ (points). The solid lines represent fits to $F_2$ in bins of $x$ according to a polynomial $P_2(x, Q^2) = a(x)+b(x)\ln Q^2+c(x)(\ln Q^2)^2$. The dashed lines are obtained from the NLO QCD fit to the H1 data (Sect. 7.2), for $Q^2 \geq 3.5$ GeV$^2$. The error bands are due to the experimental and model uncertainties in the QCD fit

in [56] in view of possible non-linear gluon interaction effects [7]. A study of the derivative $(\partial F_2/\partial \ln Q^2)_x$ at low $x$ was presented previously by the ZEUS Collaboration [57] where $F_2(x, Q^2)$ was assumed to depend linearly on $\ln Q^2$. This approximation is inconsistent with the data presented here, as can be deduced from Fig. 10. Fits with $c(x) = 0$ yield $\chi^2/dof$ values about twice as large as the quadratic fit, (12).

Using the procedure adopted for the derivatives $(\partial\sigma_r/\partial \ln y)_{Q^2}$ (Sect. 5.1) the local derivatives $(\partial F_2/\partial \ln Q^2)_x$ are measured. The results are shown in Fig. 11 for different $x$ as a function of $Q^2$, and the values are quoted in Tables 16, 17 and 18. For each bin of $x$ these derivatives can be described by the function $b(x) + 2 \cdot c(x) \ln Q^2$ (solid lines). Small deviations of $(\partial F_2/\partial \ln Q^2)_x$ from the linearity in $\ln Q^2$ occur in NLO QCD (dashed lines). Using the linear expression the derivatives are calculated at

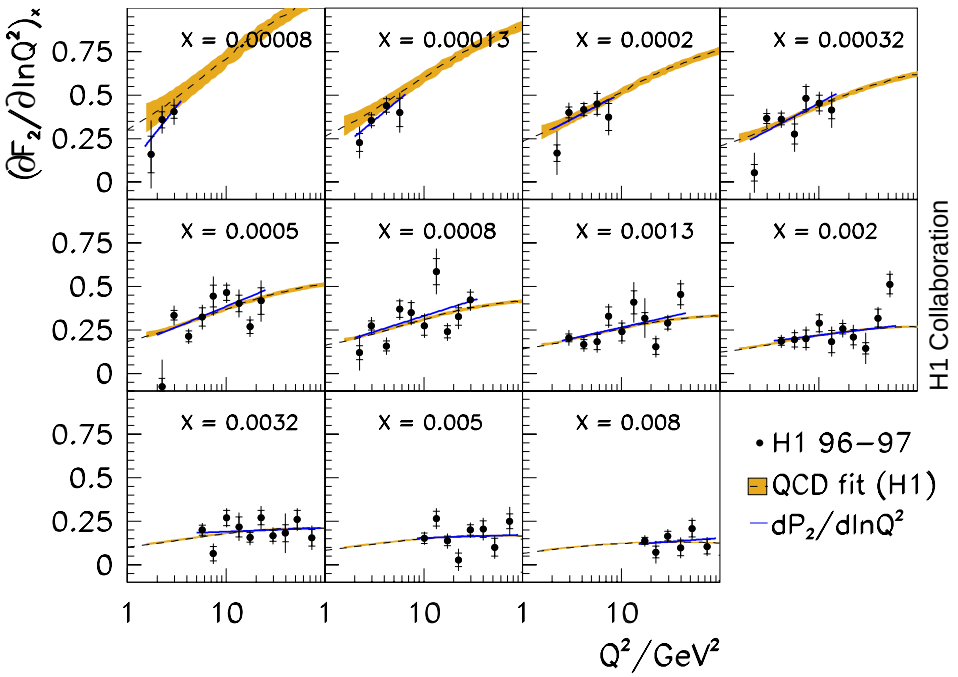

**Fig. 11.** Measurement of the partial derivative $(\partial F_2/\partial \ln Q^2)_x$ taken at fixed $x$ and plotted as functions of $Q^2$. The error bars represent the quadratic sum of statistical and systematic errors. The straight solid lines are given by the function $b(x) + 2c(x) \ln Q^2$ determined in fits to $F_2(x, Q^2)$ at fixed $x$. The dashed lines represent the derivatives as calculated with the QCD fit to the H1 data. The error bands are due to the experimental and model uncertainties in the QCD fit which includes data for $Q^2 \geq 3.5$ GeV$^2$

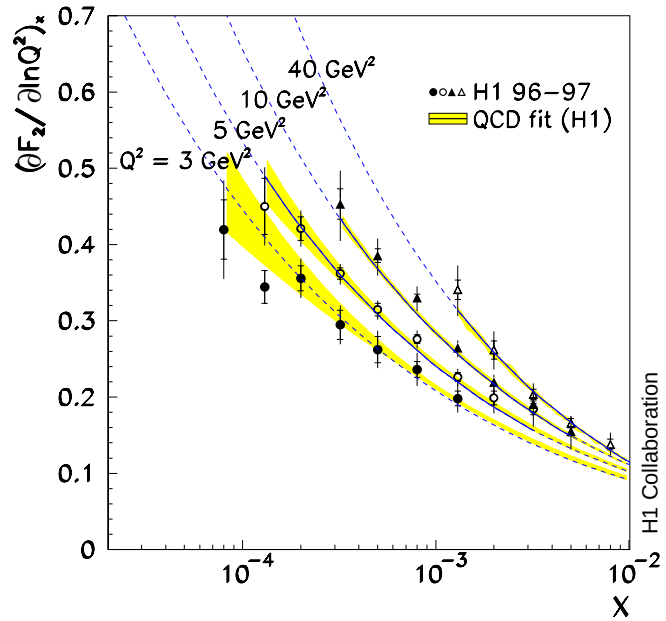

**Fig. 12.** The derivative $(\partial F_2/\partial \ln Q^2)_x$ plotted as functions of $x$ for fixed $Q^2$, for the H1 data (symbols) and the QCD fit to the H1 data, for $Q^2 \geq 3.5$ GeV$^2$ (solid lines). The dashed curves extrapolate this fit below $Q^2_{min}$ and outside the range of $x$. The error bands represent the model uncertainty of the QCD analysis

fixed $Q^2 \geq 3\,\mathrm{GeV}^2$ and are shown as functions of $x$ in Fig. 12. The derivatives show a continuous rise towards low $x$ for fixed $Q^2$ which is well described by the NLO DGLAP QCD to the H1 data (Sect. 7.2). The shape of $(\partial F_2/\partial \ln Q^2)_x$ reflects the behaviour of the gluon distribution in the associated kinematic range.

## 7 QCD analysis

In this section the predictions of the DGLAP evolution equations in NLO are confronted with the reduced differential cross section measurement. By comparison to the cross section data, the strong coupling constant $\alpha_s$, and the shape and normalisation of the gluon and quark distributions are determined. This is done using a $\chi^2$ minimisation procedure (fit) and a suitable choice of parameterisations for the input parton distributions at an initial scale $Q^2_0$.

Traditionally, this kind of analysis makes use of both lepton-proton and lepton-deuteron data [58–62] in order to separate the non-singlet and singlet evolution, and also to determine the parton distributions of up and down quarks simultaneously. The present analysis introduces a new parameterisation of quark distributions which permits lepton-proton data to be analysed alone. Thus the use of deuteron scattering data, which involves bound state corrections and their uncertainties, is avoided.

Two complete analyses are performed, one with H1 data only to determine the gluon distribution $xg(x, Q^2)$ at low $x$, and a second one in which the H1 data are combined with data from the BCDMS experiment in order to simultaneously determine the strong coupling constant $\alpha_s(M_Z^2)$ and the gluon distribution.

The most difficult aspect of these fits is an adequate treatment of systematic errors, which lead to strong correlations among the data points. The present analysis uses a sophisticated treatment of systematic error correlations allowing their true effect on the extracted quantities to be estimated by the fit [52]. This procedure is used to identify data regions which are strongly affected by correlated systematic errors. The present analysis is therefore based on a minimum number of data sets in regions where their

systematic errors are well understood. Uncertainties due to physics and analysis assumptions are estimated by a systematic exploration of the parameter space.

The $Q^2$ evolution of parton distributions is the result of processes of radiation from gluons which dominate the scaling violations at small $x \leq 0.1$, and from quarks which dominate at large $x$. The present H1 data allow the gluon contribution to be well determined for fixed $\alpha_s$. The strong correlation between the gluon distribution with $\alpha_s$ can be much reduced by using DIS data at large $x$ and low $Q^2$, in addition to the H1 data. Thus, the analysis is extended to include the precise $\mu p$ data at large $x$ from the BCDMS collaboration. This allows the gluon distribution and $\alpha_s$ to be determined simultaneously.

### 7.1 Analysis procedure

In the quark-parton model, the proton structure function $F_2(x, Q^2)$ is given by a sum of quark and anti-quark momentum distribution functions

$$F_2(x, Q^2) = x \sum_q Q_q^2 \cdot [q(x, Q^2) + \overline{q}(x, Q^2)], \qquad (13)$$

where $Q_q$ represents the electric charges of quarks. In the present analysis, the sum extends over up, down and strange ($u$, $d$, $s$) quarks. The charm and beauty contributions are added using NLO QCD calculations [63] using $m_c = 1.4\,\mathrm{GeV}$ and $m_b = 4.5\,\mathrm{GeV}$. At low $x$ about 20-30% of the inclusive cross section is due to charm production, dominated by the photon-gluon fusion process.

The present QCD analysis, described in detail in [43], uses a flavour decomposition of $F_2(x, Q^2)$ into two independent combinations of parton distribution functions $V(x, Q^2)$ and $A(x, Q^2)$, according to

$$F_2 = \frac{1}{3} xV + \frac{11}{9} xA. \qquad (14)$$

The $x$ dependences of $xg$, $V$ and $A$ are parameterised at an initial scale $Q_0^2$, and a $\chi^2$ minimisation determines these distributions and $\alpha_s$. The function $V$ is defined by the valence-quark distributions, i.e.

$$V = \frac{9}{4} u_v - \frac{3}{2} d_v. \qquad (15)$$

It is thus constrained by the relation

$$\int_0^1 V dx = 3, \qquad (16)$$

which is used in the fit procedure together with the momentum-sum rule. The function $A$ contains the sea-quark distribution and a small valence-quark correction. It is given as

$$A = \overline{u} - \frac{1}{4}(u_v - 2d_v), \qquad (17)$$

and determines the low $x$ behaviour of $F_2(x, Q^2)$.

These equations hold for a strange contribution $s + \overline{s} = (\overline{u} + \overline{d})/2$ and flavour symmetry of the sea, $u_{sea} = \overline{u} = d_{sea} = \overline{d}$. This ansatz is generalised in Appendix A.1 to account for the observed small deviations of the strange [64] and antiquark [65] distributions from the conventional assumptions about the sea. In the analysis target-mass corrections are applied using the integral relations for $F_2$ and $F_L$ as given in [66].

The analysis is performed in the $\overline{MS}$ renormalisation scheme using the DGLAP evolution equations [4] in NLO [67]. Thus the formulae for $F_2$ given here are modified by replacing the sums over parton distributions by sums over integrals of products of coefficient functions times parton distributions.

The strong coupling constant is defined by the solution of the renormalisation group equation to order $\alpha_s^3$,

$$\frac{da_s}{d\ln\mu_r^2} = -\beta_0 a_s^2 - \beta_1 a_s^3, \qquad (18)$$

where $a_s = \alpha_s/4\pi$, $\mu_r$ is the renormalisation scale, and the $\beta$ functions are defined in [67]. The longitudinal structure function is calculated to order $\alpha_s^2$. The analysis uses an $x$ space program developed inside the H1 collaboration [68, 69]. This program has been checked in detail against different evolution codes [70, 60, 71], and very good agreement is found.

In the fit procedure, a $\chi^2$ function is minimised which is defined in Appendix A.2. This definition takes into account correlations of data points caused by systematic uncertainties. It is desirable that the fit results depend neither significantly on the functional form of the parameterisations which are used for the input distributions, nor on the input scale $Q_0^2$ at which these are defined. Thus, for each fit described below, a grid of nearly $10^3$ initial fit conditions is considered, with about tenfold variations of each of the parameters $Q_0^2$, $Q_{min}^2$ and $\alpha_s$. Here $Q_{min}^2$ denotes the smallest $Q^2$ value of data included in the fit.

The quality of the fits is studied in a statistical evaluation of the parameter space for all data sets and parton distribution parameterisations considered. As described in Appendix A.3, this leads to a best choice of

$$xq(x) = a_q x^{b_q}(1-x)^{c_q}[1 + d_q\sqrt{x} + e_q x], \qquad (19)$$

for the parameterisations of the functions $V$, $A$ and $xg$. The standard value of $Q_0^2$ is 4 GeV$^2$, but it can be varied over a reasonable range without significantly influencing the result.

### 7.2 Fit to H1 Data and determination of the gluon distribution

The measurements of the reduced differential cross section presented here are combined with recent data of the H1 collaboration [12] from the same data taking period, which cover the large $x$ range at high $Q^2 \geq 150\,\mathrm{GeV}^2$. A cut $Q^2 \leq 3000$ GeV$^2$ is applied to eliminate the region where electroweak interference effects are important, which involve the structure function $xF_3$. Since the H1 data have still limited precision at large $x$, the parameter

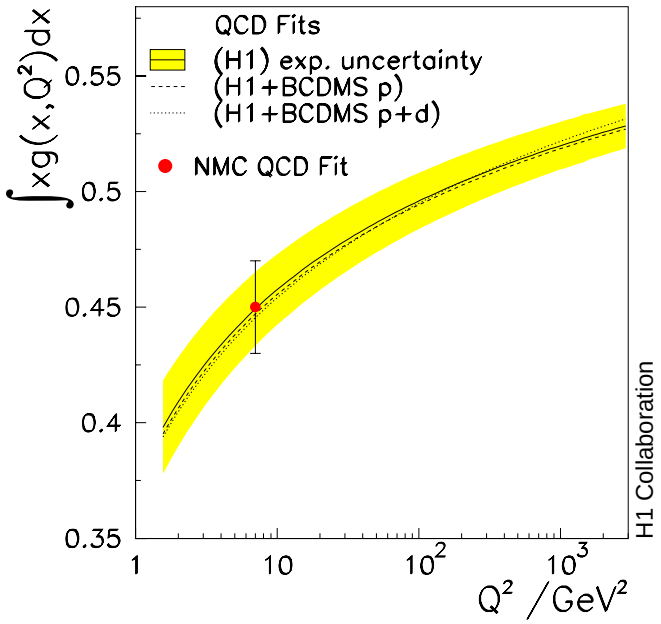

**Fig. 13.** The fraction of the proton momentum carried by gluons as a function of $Q^2$, obtained in different NLO DGLAP fits. Solid curve: fit to H1 data alone; dashed curve: fit to H1 and BCDMS proton data; dotted curve: fit to H1 $ep$ and BCDMS $\mu p$ and $\mu d$ data. The shaded error band represents the experimental uncertainty in the analysis of the H1 data alone. The solid point is due to a QCD analysis by the NMC collaboration [58]

$d_g$ in the expression for the gluon distribution (19) is superfluous, see Appendix A.3. For the fits to the H1 data alone it is therefore set to $d_g = 0$.

The standard fit assumes a fixed $\alpha_s(M_Z^2) = 0.115$ and uses all H1 data for $Q^2 \geq 3.5$ GeV$^2$. In this range derivatives of $F_2$ with respect to $\ln Q^2$ are measured and found to be described by the DGLAP evolution equations (see Sect. 6). The momentum fraction carried by the gluons is $0.43 \pm 0.02$ $(exp)$ at the input scale $Q_0^2 = 4$ GeV$^2$ where the error is due to the measurement uncertainties. The variation of the gluon momentum fraction with $Q^2$ is shown in Fig. 13. The result agrees with previous determinations at $Q^2 = 7$ GeV$^2$ [58, 72]. The stability of this result has been checked by adding $\mu p$ and also $\mu d$ data of the BCDMS collaboration. As is shown in Fig. 13, no significant change is observed. The fit is also repeated without using the constraint given by the momentum sum rule. This fit determines the integral $\int_0^1 x(\Sigma + g)dx$ to be $1.016 \pm 0.017(exp)$, where $\Sigma$ is the singlet parton distribution function, see Appendix A.3. This value is found to be nearly independent of the minimum $Q^2$ value of the data included in the analysis.

The structure function $F_2(x, Q^2)$ is extracted from the reduced cross section data using the prediction of the fit for the longitudinal structure function $F_L(x, Q^2)$. The result is shown in Figs. 14 and 15. The data are compared to published $\mu p$ data of the fixed target muon-proton scattering experiments BCDMS and NMC. The solid lines give the result of the QCD fit with $Q^2_{min} = 3.5$ GeV$^2$ to the H1 data. This fit also describes the fixed target data in the non-overlapping regions rather well, except for the data points at $x = 0.65$ where the fit curve is below the BCDMS data. The H1 data at this value of $x$ [12] have a correlated systematic uncertainty of 12%, due to the energy scale error for the scattered positron, which accommodates the observed difference.

The $x$ range is restricted at small $x$ by the choice of $Q^2_{min}$. An extension of the analysis to low values of $Q^2$ and $x$ is of interest to study possible deviations from NLO DGLAP evolution. The dependence of the fit result on the chosen $Q^2_{min}$ is studied systematically. Figure 16 shows the H1 $F_2$ data for $x \leq 8 \cdot 10^{-4}$ together with the fit curves for different values of $Q^2_{min}$. The fit with $Q^2_{min} = 1.5$ GeV$^2$ describes all the data very well. If $Q^2_{min}$ is raised, the fit curves extrapolated below $Q^2 = Q^2_{min}$ tend to undershoot the data excluded from the fit. The gluon distributions at $Q^2 = 5$ GeV$^2$ obtained from these fits are shown in Fig. 17 in the low $x$ range where the gluon distribution is constrained[1]. They are consistent within the estimated uncertainty in the overlapping regions. Extension of this study into the region of $Q^2 \simeq 1$ GeV$^2$ is of interest. It requires precision data in a large range of $x$. For such $Q^2$ values the gluon distribution $xg(x, Q^2)$, in twist 2 NLO QCD, is observed to approximately vanish at low $x$ acquiring a valence-like shape.

The fit to the H1 data determines $\alpha_s(M_Z^2)$ to be 0.115 with an experimental error of $\pm 0.005$ and an optimum $\chi^2$ of 180 for 224 degrees of freedom. This is the first measurement of $\alpha_s$ with HERA inclusive cross section data alone. The result for the gluon distribution obtained from the H1 measurements is shown in Fig. 18. The innermost error band is due to the experimental measurement uncertainty, which for $3 \cdot 10^{-4} \leq x \leq 0.1$ is about 5% and decreases to about 3% at $Q^2 = 20$ GeV$^2$. The middle error band illustrates the effect of an $\alpha_s$ uncertainty of $\pm 0.0017$, which is derived in the fit to the combined H1 and BCDMS data (see below). The outer error band includes in addition the uncertainty of the QCD model as described subsequently. For values of $x > 0.1$ this analysis is not able to reliably determine the shape of the gluon distribution because in this range the scaling violations are dominated by quark radiation rather than gluon radiation. Yet, the integrated momentum fraction carried by gluons at large $x$ is constrained by the momentum sum rule as discussed above. The fit determines this contribution to be $\int_{0.1}^1 xg(x, Q^2)dx = 0.13 \pm 0.04$ $(exp)$ for $Q^2 = 4$ GeV$^2$.

The result for the gluon distribution depends on the theoretical framework since $xg$ is not an observable. For example, if the massive quark description for charm and beauty production is replaced by the massless treatment of heavy quarks, the gluon distribution changes as illustrated

[1] The measurement of the slope $(\partial F_2/\partial \ln Q^2)_x$ requires at least two data points with different $Q^2$ above $Q^2_{min}$ for fixed $x$. Thus the minimum value $x_{min}$ at which this slope can be measured depends on $Q^2_{min}$. It has been shown in [55] that the derivative $(\partial F_2/\partial \ln Q^2)_x$ determines the gluon distribution at a value of approximately $2x$. The gluon distributions in Fig. 17 are therefore shown only down to $x \simeq 2x_{min}$

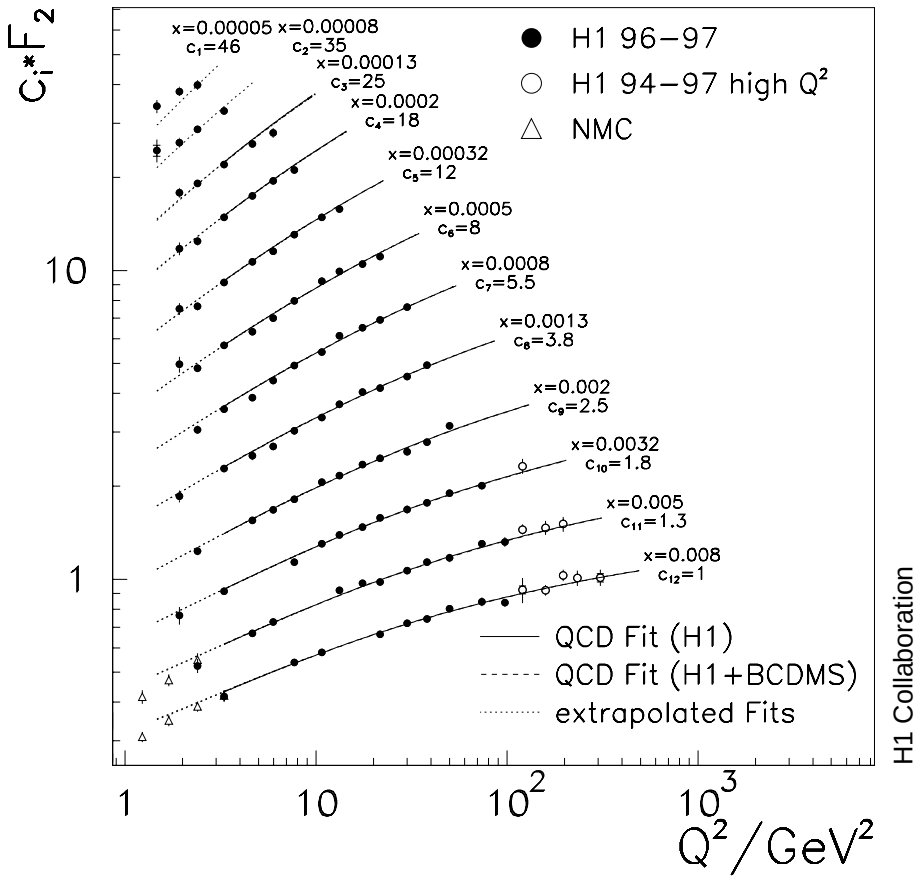

**Fig. 14.** Measurements of the proton structure function $F_2(x, Q^2)$ by the H1 and the NMC experiments. Solid curves: NLO DGLAP QCD fit to the H1 cross section data. Overlayed as dashed curves are the results of the QCD fit to the H1 $ep$ and BCDMS $\mu p$ data, for $y_\mu > 0.3$, which are indistinguishable from those of the pure H1 fit. Dotted curves: fit extrapolations at fixed $x$ into the region below $Q^2 = 3.5$ GeV$^2$

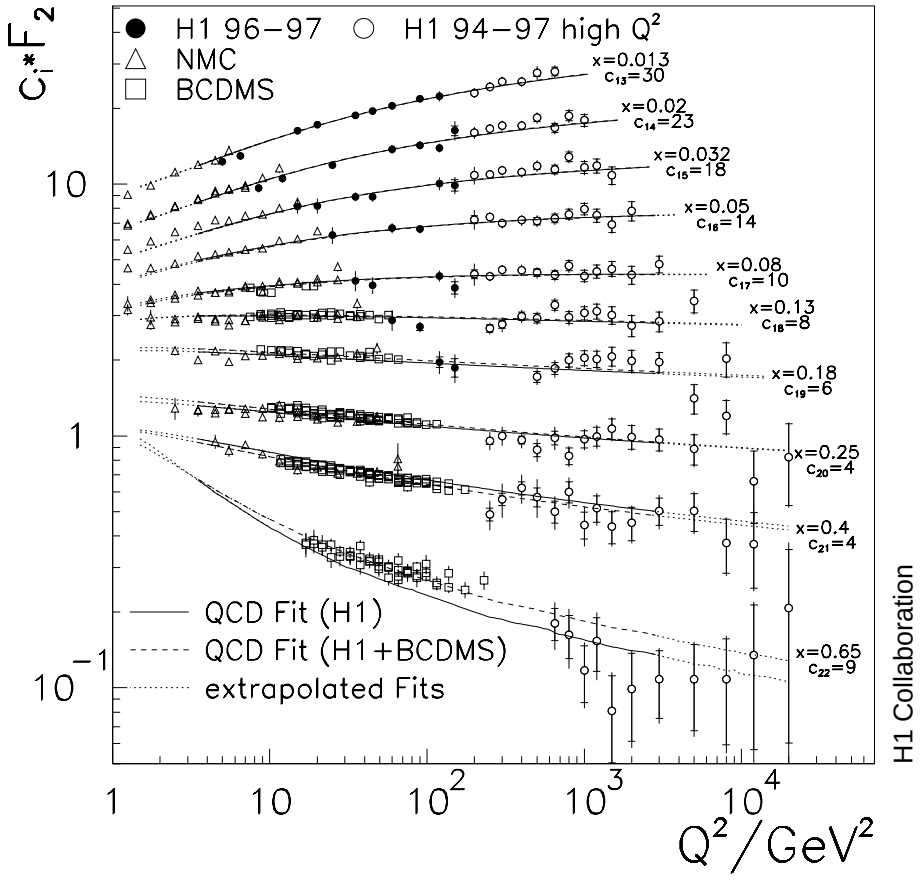

**Fig. 15.** Measurements of the proton structure function $F_2(x, Q^2)$ by the H1 experiment and by fixed target muon-proton scattering experiments. The error on the data points is the total measurement uncertainty. The inner error bars represent the statistical error. Solid curves: fit to the H1 cross section data. Dashed curves: fit to the H1 $ep$ and BCDMS $\mu p$ data, for $y_\mu > 0.3$. Dotted curves: extrapolations to data not used in the fit

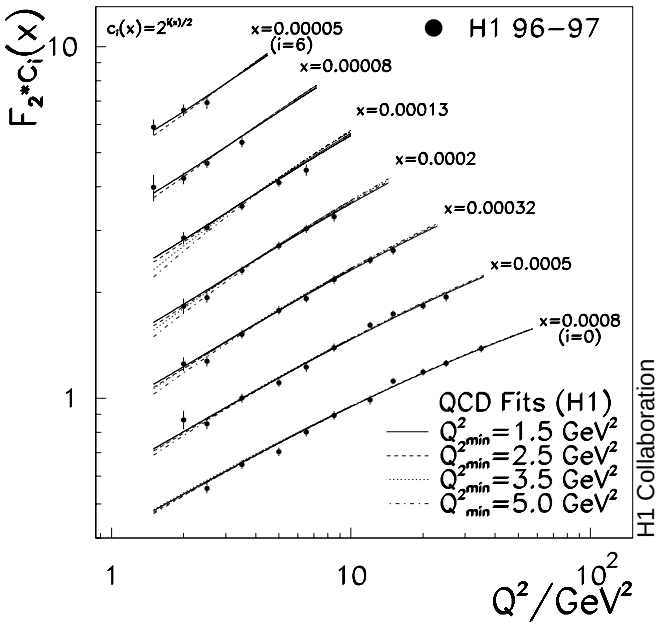

**Fig. 16.** Effect of the $Q^2_{min}$ cut on the structure function $F_2$ in the DGLAP QCD fit to the H1 data (points). The curves represent fits with different minimum $Q^2$ values. The analysis uses $Q^2_{min} = 3.5\,\mathrm{GeV}^2$ as default

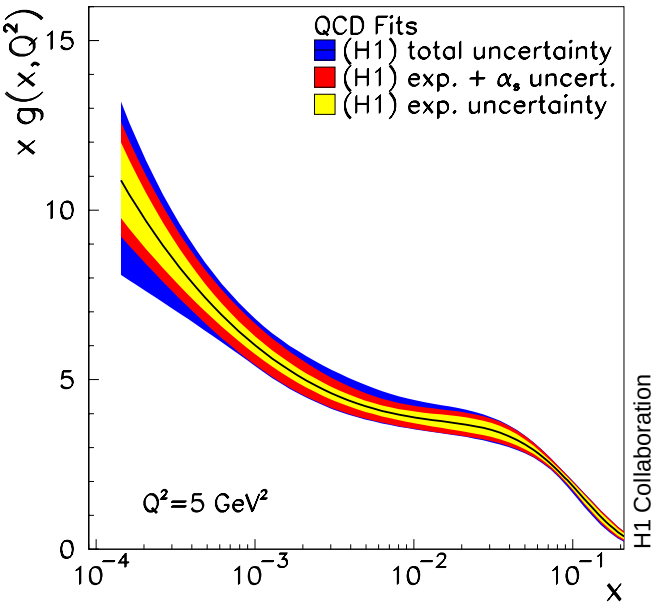

**Fig. 18.** The gluon distribution $xg(x, Q^2)$ at $Q^2 = 5$ GeV$^2$, determined in the NLO DGLAP QCD fit to the H1 data. Inner error band: experimental uncertainty; middle error band: effect of the experimental error and of the $\alpha_s(M_Z^2)$ uncertainty of $\pm 0.0017$; outer error band: effect of experimental, $\alpha_s$ and model uncertainties

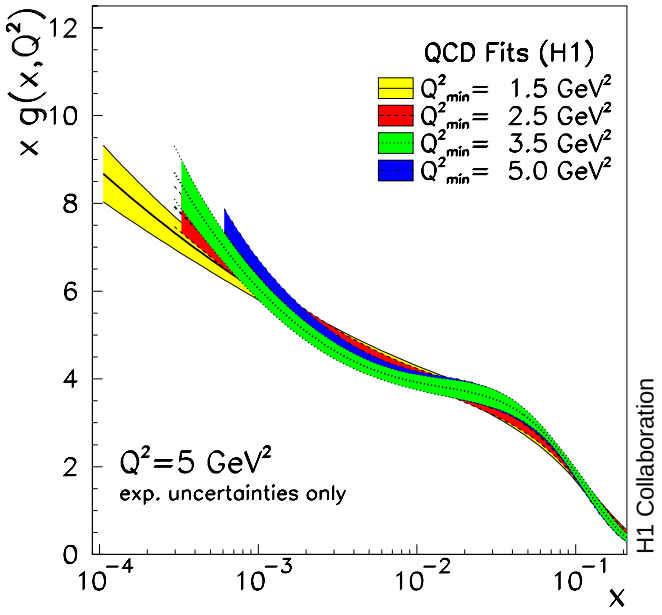

**Fig. 17.** Effect of the $Q^2_{min}$ cut, applied in the DGLAP QCD fit to the H1 data, on the gluon distribution at $Q^2 = 5$ GeV$^2$. The error bands represent the uncertainty of $xg$ resulting from the measurement uncertainties only. The gluon distributions are shown down to $x$ values corresponding to twice the minimum $x$ values of the data which allow a $Q^2$ slope to be measured

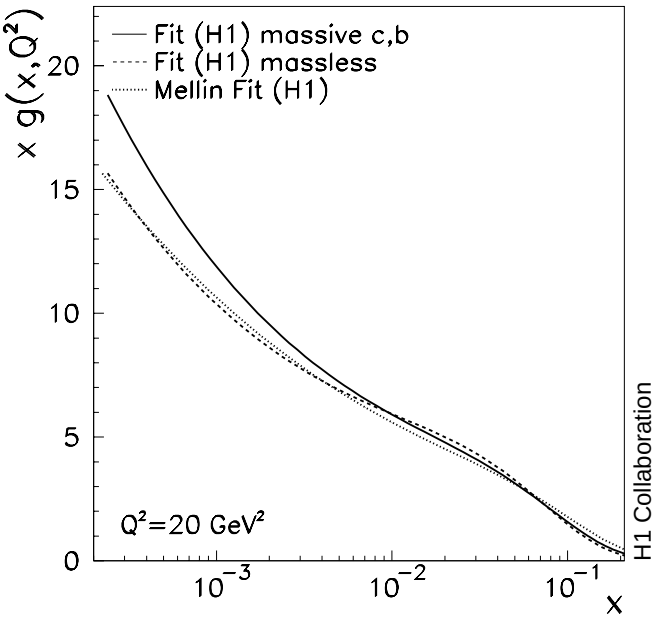

**Fig. 19.** Comparison of gluon distributions obtained in NLO DGLAP QCD fits to the H1 data, using different prescriptions: solid curve: standard fit using the massive heavy flavour scheme; dashed curve: fit in the massless scheme; dotted curve: fit in the massless scheme using a Mellin $n$ space program

in Fig. 19. The gluon distribution in the massless fit is about 15% lower at small $x$ compared to the standard result. A consistent cross check of this massless fit result is obtained with a Mellin $n$ space program [73].

The analysis of the longitudinal structure function $F_L$ (Sect. 5.2) uses a QCD fit to the reduced cross section for $y \leq 0.35$. This fit follows exactly the same procedure as that described above. It results in a $\chi^2$ of 151 for 180 degrees of freedom and agrees very well with the full fit. In particular, the gluon distribution obtained in this fit is nearly indistinguishable from $xg$ obtained in the standard fit covering the full $y$ range which is sensitive to $F_L$. Thus, $xg(x, Q^2)$ appears to be determined by the scaling violations of $F_2(x, Q^2)$.

### 7.3 Simultaneous determination of $\alpha_s(M_Z^2)$ and the Gluon Distribution

The precision of the large $x$, high $Q^2$ H1 data [12] is not sufficient to enable a competitive determination of $\alpha_s(M_Z^2)$ and of the gluon distribution simultaneously from the H1 data alone. The most precise measurement of the DIS inclusive cross section at large $x$ was obtained by the BCDMS $\mu p$ scattering experiment [13] (Fig. 15). These data are therefore combined with the H1 measurements.

In a first step, a fit is performed to the complete data sets. The correlated systematic errors of the data are fitted, together with the other parameters. Regions of data are identified in which the fit causes large systematic shifts of the data points. For the BCDMS data in the range $y_{BCDMS} = y_\mu < 0.3$ the data points are shifted by more than the quoted systematic error. The low $y$ region in this experiment is particularly strongly affected by the energy scale uncertainty of the scattered muon, which leads to correlated systematic errors $\propto 1/y$. These become large at low $y$ for each of the four data sets at different muon energy. Note that the low $y$ data of BCDMS differ from measurements of the $ep$ scattering cross section at SLAC [74,75] in the region of overlap. In this region the BCDMS data accuracy is dominated by systematic errors while the SLAC measurement is statistically limited. This also suggests the presence of large systematic effects in the low $y$ region of the BCDMS data which were studied previously [76]. Therefore in all analyses only BCDMS data with $y_\mu > 0.3$ are used.

The result of the QCD fit to the combined H1 and BCDMS data sets, leaving $\alpha_s$ as a free fit parameter, is shown in Figs. 14 and 15 as dashed curve. It describes the data very well with a $\chi^2$/dof of 394/451. The fit to the H1 and BCDMS data is nearly indistinguishable from the fit to the H1 data alone, except for the two highest $x$ bins. The parameterisations used in the fit to the H1 and BCDMS data are given in (19), and the parameters are summarised in Table 5. The choice of these particular shapes results from a detailed analysis of the behaviour of the $\chi^2$ function, similar to the fit to the H1 data which is described in Appendix A.3.

The $\alpha_s$ value obtained in the NLO analysis of the H1 and BCDMS proton data is

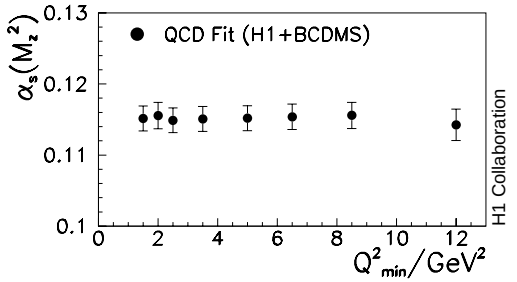

**Fig. 20.** Dependence of $\alpha_s(M_Z^2)$ obtained in fits to the H1 and BCDMS data on the minimum $Q^2$ value used. The error bars denote the experimental uncertainty of $\alpha_s(M_Z^2)$. Note that the BCDMS data have an intrinsic $Q^2_{min}$ of 7.5 GeV$^2$ and are limited in this analysis to $y_\mu \geq 0.3$ (see text). An increase of $Q^2_{min}$ implies that the minimum $x$ rises correspondingly, i.e. from $x = 3.2 \cdot 10^{-5}$ at $Q^2_{min} = 1.5\,\text{GeV}^2$ to $x = 8 \cdot 10^{-4}$ at $Q^2_{min} = 12\,\text{GeV}^2$

**Table 5.** Parameters of the input distributions $xq(x) = a_q x^{b_q}(1-x)^{c_q}[1 + d_q\sqrt{x} + e_q x]$ for $xg(x, Q^2)$, $V(x, Q^2)$ and $A(x, Q^2)$ at the initial scale $Q_0^2 = 4$ GeV$^2$ using H1 and BCDMS data for $Q^2 \geq 3.5$ GeV$^2$ and $y_\mu > 0.3$. A fit with $d_g = e_g = 0$ yields $c_g = 6.5$, not far from the dimensional counting rule expectation [77], yet with a worsened $\chi^2$

| | a | b | c | d | e |
|---|---|---|---|---|---|
| gluon | 1.10 | -0.247 | 17.5 | -4.83 | 68.2 |
| V | 86.3 | 1.47 | 4.48 | -2.12 | 1.60 |
| A | 0.229 | -0.130 | 19.7 | -3.82 | 29.8 |

$$\alpha_s(M_Z^2) = 0.1150 \pm 0.0017\ (exp)\ {}^{+\ 0.0009}_{-\ 0.0005}\ (model). \quad (20)$$

In this combined fit both data sets consistently favour a value of $\alpha_s(M_Z^2) \simeq 0.115$ with comparable accuracy. The first error represents the experimental uncertainty of the data sets. The second error includes all uncertainties associated with the construction of the QCD model for the measured cross section. These are summarised in Table 6. The strong coupling constant is defined here by the solution of the renormalisation group equation to order $\alpha_s^3$. In the double logarithmic approximation the value for $\alpha_s(M_Z^2)$ is calculated to be lower by 0.0003.

The value obtained for $\alpha_s(M_Z^2)$ is nearly independent of $Q_0^2$ and of the chosen parameterisation for the large set of input distributions considered in Appendix A.3. Residual effects are included in the estimation of the systematic error on $\alpha_s$. The dependence of $\alpha_s$ on $Q^2_{min}$ is shown in Fig. 20. No systematic trend is observed. Note that the BCDMS data are limited to $Q^2 \geq 7.5$ GeV$^2$, such that a choice of $Q^2_{min}$ below this value affects the low $x$ H1 data only.

The combination of low $x$ data with high $x$ data constrains the gluon distribution and $\alpha_s$. A correlation is observed (Fig. 21) between $\alpha_s$ and the parameter $b_g$, which governs the shape of the gluon distribution at low $x$ (19). In a fit to the BCDMS data alone, for $y_\mu > 0.3$ and using $xg = ax^b(1-x)^c$, a value of $\alpha_s(M_Z^2) = 0.111 \pm 0.003$ ($exp$)

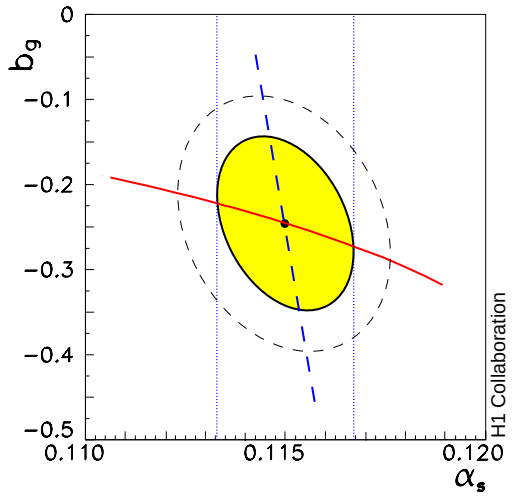

**Fig. 21.** The correlation of the gluon distribution parameter $b_g$ with $\alpha_s$ in the fit to H1 and BCDMS data. The parameter $b_g$ governs the low $x$ behaviour of $xg(x,Q_0^2) \propto x^{b_g}$ for the chosen $Q_0^2 = 4\,\mathrm{GeV}^2$. The solid (dashed) ellipse marks the $\chi^2+1$ ($\chi^2+2.3$) contour around the minimum of $\chi^2$. The solid (dashed) line indicates the resulting value of $b_g$ ($\alpha_s$) for a given $\alpha_s$ ($b_g$) when all parameters but the latter are allowed to vary in the minimisation procedure. The correlation coefficient of $b_g$ and $\alpha_s$ is -0.25

is found[2], and $b_g$ is positive. A positive value of $b_g$ implies that $xg(x,Q_0^2)$ falls as $x$ decreases. An early $\alpha_s$ analysis [59], in the absence of detailed information about the low $x$ behaviour of $xg$, assumed $b_g = 0$. A positive or zero value of $b_g$, for $Q_0^2 \geq 4\,\mathrm{GeV}^2$, is found to be incompatible with the data which is consistent with previous studies [75]. The fit to the BCDMS data, when complemented with low $x$ H1 data, leads to a negative $b_g$ parameter, and therefore a larger value of $\alpha_s(M_Z^2)$ is obtained with the BCDMS data than hitherto. The results of these fits to the H1 and BCDMS data are shown in Fig. 22a. In the combined fit both data sets give a consistent and comparable contribution to the error on $\alpha_s$. This is illustrated in Fig. 22b.

A rather large theoretical uncertainty of the NLO analysis results from the choices of the renormalisation scale $\mu_r^2 = m_r \cdot Q^2$ (18), and of the factorisation scale $\mu_f^2 = m_f \cdot Q^2$ which leads to scale dependent parton distributions. In the $\overline{MS}$ scheme both scales are set equal to $Q^2$, i.e. $m_r = m_f = 1$. In the absence of a clear theoretical prescription, the effect of both scales on $\alpha_s$ is estimated by varying the scale factors $m_r$ and $m_f$ between 0.25 and 4. The results are summarized in Table 7. In agreement with previous studies [62] it is found that the renormalisation scale causes a much larger uncertainty on $\alpha_s(M_Z^2)$ than the factorisation scale. Depending on which set of $m_r$ and $m_f$ is chosen, the obtained $\chi^2$ differs by several units. This suggests that the assumed variation of the scales is too large. These scales, however, are not considered to represent physics quantities which may be determined in the minimisation procedure. The estimated overall uncertainty of about 0.005 on $\alpha_s(M_Z^2)$ is much larger than the experimental error. It is expected to be significantly reduced when next-to-NLO calculations become available [78,71]. Recently an $\alpha_s$ analysis of moments of structure functions, measured in charged lepton-nucleon scattering, was presented extending to NNLO QCD [79].

The stability of the fit results is checked further with respect to possible changes in the analysis procedure:

- The value of $\alpha_s(M_Z^2)$ increases by 0.0005 if the correlation due to systematic errors is neglected, i.e. if the correlated systematic error parameters are not part of the minimisation (see Appendix A.2).
- In the present analysis, the relative normalisations of the data sets are left free. The change imposed by the fit to the BCDMS data is about −1.5% within a total normalisation uncertainty of 3%. The H1 data are moved by about 1% within the experimental error

[2] The requirement $y_\mu > 0.3$ causes $\alpha_s(M_Z^2)$ to increase by about 0.004 in the fit to the BCDMS data only, and by about 0.002 in the fit to the H1 and BCDMS data combined

**Table 6.** Contributions to the error of $\alpha_s(M_Z^2)$ in the analysis of H1 $ep$ and BCDMS $\mu p$ data which are due to the selection of data and to the fit assumptions

| analysis uncertainty | $+\delta\ \alpha_s$ | $-\delta\ \alpha_s$ |
|---|---|---|
| $Q^2_{min} = 2\ \mathrm{GeV}^2$ | | 0.00002 |
| $Q^2_{min} = 5\ \mathrm{GeV}^2$ | 0.00016 | |
| parameterisations | 0.00011 | |
| $Q_0^2 = 2.5\ \mathrm{GeV}^2$ | 0.00023 | |
| $Q_0^2 = 6\ \mathrm{GeV}^2$ | | 0.00018 |
| $y_e < 0.35$ | 0.00013 | |
| $x < 0.6$ | 0.00033 | |
| $y_\mu > 0.4$ | 0.00025 | |
| $x > 5 \cdot 10^{-4}$ | 0.00051 | |
| uncertainty of $\overline{u} - \overline{d}$ | 0.00005 | 0.00005 |
| strange quark contribution $\epsilon = 0$ | 0.00010 | |
| $m_c + 0.1\,\mathrm{GeV}$ | 0.00047 | |
| $m_c - 0.1\,\mathrm{GeV}$ | | 0.00044 |
| $m_b + 0.2\,\mathrm{GeV}$ | 0.00007 | |
| $m_b - 0.2\,\mathrm{GeV}$ | | 0.00007 |
| total uncertainty | 0.00088 | 0.00048 |

**Table 7.** Dependence of $\alpha_s(M_Z^2)$ on the renormalisation and factorisation scales $m_f$ and $m_r$, respectively, expressed as the difference of $\alpha_s(M_Z^2)$ obtained for scales different from one and the central value of $\alpha_s(M_Z^2)$ =0.1150. The combination $m_f = 4$ and $m_r = 0.25$ is abandoned since the splitting function term $\propto \ln(m_r/m_f)^2$ becomes negative at low $Q^2$ which causes a huge increase of $\chi^2$

| | $m_r = 0.25$ | $m_r = 1$ | $m_r = 4$ |
|---|---|---|---|
| $m_f = 0.25$ | −0.0038 | −0.0001 | +0.0043 |
| $m_f = 1$ | −0.0055 | – | +0.0047 |
| $m_f = 4$ | – | +0.0005 | +0.0063 |

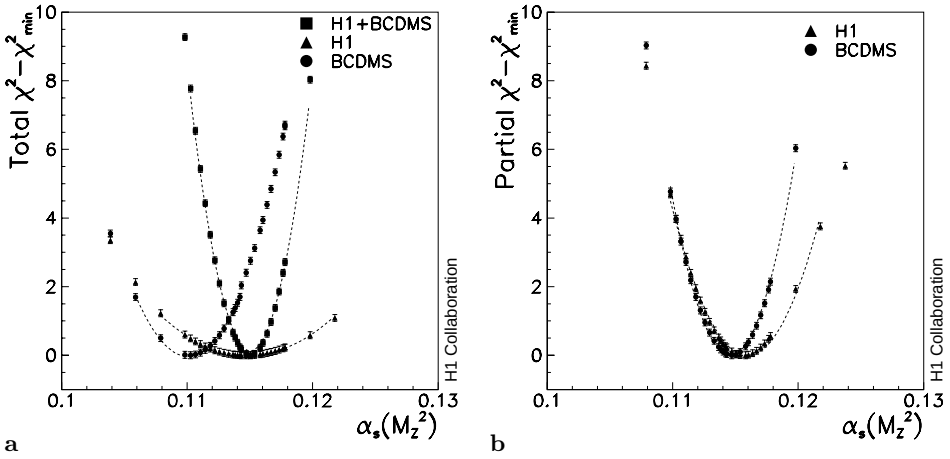

**Fig. 22a,b.** Determination of the strong coupling constant $\alpha_s(M_Z^2)$ in NLO DGLAP QCD. **a** total $\chi^2$ for fits to the H1 $ep$ and BCDMS $\mu p$ data ($y_\mu > 0.3$) separately and for the fit using data of the two experiments combined; **b** partial $\chi^2$ contributions of the H1 and BCDMS proton data in the fit to determine $\alpha_s$ using both experiments

of 1.7%. Thus the selected H1 and BCDMS data are compatible with each other. If the fit is repeated with all normalisations fixed then $\chi^2$ increases by 26, and $\alpha_s(M_Z^2)$ increases by 0.0005.

– If the BCDMS data is replaced by data of the NMC collaboration [80], imposing the low $Q^2$ limit of the BCDMS data, a consistent value of $\alpha_s(M_Z^2) = 0.116 \pm 0.003$ ($exp$) is obtained.
– If the heavy flavour treatment is changed and a massless, four flavour fit performed, $\alpha_s(M_Z^2)$ is enlarged by $+0.0003$.
– The addition of the BCDMS deuteron target data, with $y_\mu > 0.3$, to the H1 and BCDMS proton data yields $\alpha_s(M_Z^2) = 0.1158 \pm 0.0016$ ($exp$), i.e. $\alpha_s(M_Z^2)$ increases by 0.0008. In this analysis nuclear corrections [81] are applied, and the conventional flavour decomposition into valence and sea quarks is used.

The gluon distribution from the fit to the H1 and the BCDMS proton cross section data is shown in Fig. 23 for $Q^2 = 5\,\mathrm{GeV}^2$. The inner error band represents the experimental uncertainty of the determination of $xg$ for $\alpha_s$ fixed. This fit, however, simultaneously determines $xg(x, Q^2)$ and $\alpha_s$, which leads to a small increase of the experimental error of $xg$ as is illustrated by the middle error band. The full error band includes in addition the uncertainties connected with the fit ansatz, as listed in Table 6 for the determination of $\alpha_s(M_Z^2)$. For the low $x$ behaviour of $xg(x, Q^2)$ these are dominated by the choice of $Q^2_{min}$, as is discussed in Sect. 7.2. The gluon distribution from the combined fit is shown also for two higher $Q^2$ values, 20 and $200\,\mathrm{GeV}^2$. The DGLAP evolution leads to a gluon distribution which rises dramatically at small $x$ with increasing $Q^2$ (Fig. 23). The inner solid line illustrates the behaviour of $xg(x, Q^2)$, as determined with the H1 data alone, which is seen to be in very good agreement. The fits with deuteron data or NMC data lead to very similar gluon distributions. This analysis determines $xg$ from the scaling violations of $F_2$. It is more accurate but consistent with determinations of the gluon distribution by the H1 experiment in charm [82] and deep-inelastic dijet [83] production.

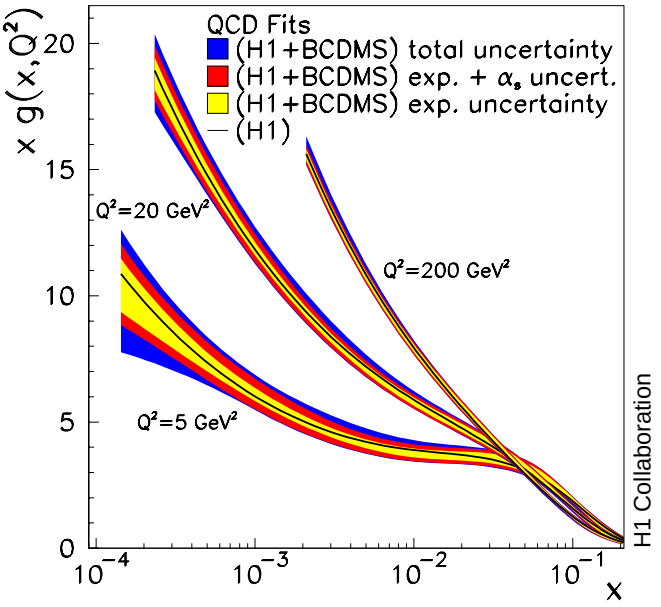

**Fig. 23.** Gluon distribution resulting from the NLO DGLAP QCD fit to H1 $ep$ and BCDMS $\mu p$ cross section data in the massive heavy flavour scheme. The innermost error bands represent the experimental error for fixed $\alpha_s(M_Z^2)$ =0.1150. The middle error bands include in addition the contribution due to the simultaneous fit of $\alpha_s$. The outer error bands also include the uncertainties related to the QCD model and data range. The solid lines inside the error band represent the gluon distribution obtained in the fit to the H1 data alone

## 8 Summary

A new measurement of the deep-inelastic positron-proton scattering cross section is presented for squared four-momentum transfers $1.5 \leq Q^2 \leq 150\mathrm{GeV}^2$ and Bjorken-$x$ values $3 \cdot 10^{-5} \leq x \leq 0.2$ which is more precise than previous measurements in this kinematic range. The statistical accuracy of the present inclusive cross section measurement is better than 1%, for a large part of the kinematic region. The systematic uncertainty has decreased to about 3%, apart from the edges of the covered range. This is due to improved detectors in the backward region

used for the identification and measurement of the scattered positrons at low $Q^2$. These are an electromagnetic calorimeter (SPACAL) with very good spatial and energy resolutions, a drift chamber (BDC) and a silicon tracker (BST).

The kinematic range is extended down to $y = 0.004$ such that the present data overlap kinematically with the measurements of muon-proton scattering experiments. This is achieved with higher statistics, improved event vertex reconstruction and calibration of the forward parts of the calorimeter. The present data agree with the $\mu p$ data in the region of overlap within the accuracy of about 7%. The kinematic range is extended also up to $y = 0.82$ using track reconstruction in front of the SPACAL in an extended angular range.

The cross section measurement is used to determine derivatives with respect to $\ln y$ and to $\ln Q^2$ as functions of $x$ and $Q^2$. The partial derivative $(\partial F_2/\partial \ln Q^2)_x$ is measured in the full $x, Q^2$ range of this measurement. When considered as a function of $x$ at fixed $Q^2$, for $3 \leq Q^2 \leq 40\ \mathrm{GeV}^2$, it is observed to rise continuously towards low $x$ in agreement with QCD.

The partial derivative of the reduced cross section $(\partial \sigma_r/\partial \ln y)_{Q^2}$ is used to extract $F_L$ at low $Q^2 < 10\,\mathrm{GeV}^2$. This is complemented by a determination of $F_L$ at $Q^2 > 10\,\mathrm{GeV}^2$ using the difference between the measured reduced cross section, $\sigma_r$, and $F_2$ calculated from an extrapolation of a NLO QCD fit to low $y$ data. Thus the longitudinal structure function $F_L$ at low $x$ is determined more precisely than hitherto, and in a larger $Q^2$ range.

A detailed, systematic analysis is presented of the structure function data using the DGLAP evolution equations in NLO. The salient features of this analysis are a new formalism for charged lepton-proton scattering and a comprehensive study of the influence of model parameters and parton distribution parameterisations on the results. These are obtained from a minimum number of data sets with special emphasis on the treatment of correlated systematic errors.

The scaling violations of $F_2$, the behaviour of the derivatives and of the longitudinal structure function at low $x$ are found to agree with DGLAP QCD. The present precise low $x$ data, when combined with high $Q^2$ data of H1 from the same running period, determine the shape of the gluon distribution at small $x$. The gluon distribution $xg(x, Q^2)$ is determined at $Q^2 = 20\,\mathrm{GeV}^2$ to an experimental accuracy of about 3% in the kinematic range $3 \cdot 10^{-4} \leq x \leq 0.1$.

A simultaneous determination of the gluon distribution and of $\alpha_s$ is obtained by combining the low $x$ data of H1 with $\mu p$ scattering data of the BCDMS collaboration at large $x$. A value of the coupling constant $\alpha_s(M_Z^2) = 0.1150 \pm 0.0017(exp)^{+\ 0.0009}_{-\ 0.0005}(model)$ is obtained. The value of $\alpha_s$ changes by about 0.005, much more than the experimental error, if the renormalisation scale is allowed to vary by a factor of four, and to a lesser extent if the factorisation scale is changed by the same amount. This uncertainty is expected to be reduced significantly in next-to-NLO perturbation theory.

*Acknowledgements.* We are very grateful to the HERA machine group whose outstanding efforts made this experiment possible. We acknowledge the support of the DESY technical staff. We appreciate the substantial effort of the engineers and technicians who constructed and maintain the detector. We thank the funding agencies for financial support of this experiment. We wish to thank the DESY directorate for the support and hospitality extended to the non-DESY members of the collaboration. We thank J. Blümlein, M. Botje, W. van Neerven, R. Roberts, and W.-K. Tung for interesting discussions on the QCD interpretation of this data. We are particularly grateful to A. Vogt for his cooperative effort in the analysis of higher-order effects on $\alpha_s$ and to R. Engel for help in the photoproduction background simulation.

## A Details of the QCD analysis

### A.1 Flavour decomposition of $F_2$

The structure function $F_2$ can be written as

$$F_2 = \frac{4}{9} \cdot xU + \frac{1}{9} \cdot xD, \tag{21}$$

with $U = u + \overline{u}$ and $D = d + \overline{d} + s + \overline{s}$ (13). A modified projection yields

$$F_2 = \frac{2}{9} \cdot x\Sigma + \frac{1}{3} \cdot x\Delta. \tag{22}$$

The sum $\Sigma = U + D$ defines a singlet combination of quark distributions which has a $Q^2$ evolution coupled to the gluon momentum distribution $xg$. The difference $\Delta = (2U - D)/3$ defines a non-singlet distribution which evolves independently of $xg$. Thus $F_2$ is defined by two independent quark distribution functions.

In this analysis two specific functions $V(x, Q^2)$ and $A(x, Q^2)$ are chosen which are related to $U$ and $D$ according to

$$U = \frac{2}{3}V + 2A \tag{23}$$

and

$$D = \frac{1}{3}V + 3A. \tag{24}$$

The inverse relations defining $V$ and $A$ are

$$V = \frac{3}{4}(3U - 2D) = \frac{9}{4}u_v - \frac{3}{2}d_v + \frac{9}{2}\overline{u} - 3(\overline{d} + \overline{s}) \tag{25}$$

and

$$A = \frac{1}{4}(2D - U) = \overline{d} + \overline{s} - \frac{1}{2}\overline{u} - \frac{1}{4}u_v + \frac{1}{2}d_v, \tag{26}$$

which for the conventional assumption $\overline{u} = \overline{d} = 2\overline{s}$ lead to the relations presented in the introduction of the QCD analysis, see Sect. 7.1. In this approximation the $V$ distribution vanishes for small $x < 0.01$. The behaviour for

large $x$ is defined by $u_v$. For small $x$ the function $A$ is given by the sea distribution $A \simeq \overline{u}$.

Recent measurements of Drell-Yan muon pair production at the Tevatron [65] have established a difference between the $\overline{u}$ and $\overline{d}$ distributions. Charged current neutrino-nucleon experiments determined the relative amount of strange quarks in the nucleon sea to be

$$s + \overline{s} = \left(\frac{1}{2} + \epsilon\right) \cdot (\overline{u} + \overline{d}), \tag{27}$$

with a recent value of $\epsilon = -0.08$ [84]. These results lead to modifications of the simple assumptions on the sea[3]. They have been accounted for by modifying (24) according to

$$D = \frac{1}{3}V + kA, \tag{28}$$

which, using (23), results in

$$V = \frac{3}{2} \cdot \frac{1}{k-1}(kU - 2D) \tag{29}$$

and $\Sigma = V + A \cdot (2 + k)$. Choosing $k = 3 + 2\epsilon$ can be shown to remove the strange contribution to the function $V$ yielding

$$V = \frac{3}{4} \cdot \frac{1}{1+\epsilon}[(3 + 2\epsilon)u_v - 2d_v + (5 + 2\epsilon)(\overline{u} - \overline{d})], \tag{30}$$

which coincides with (15) for $\epsilon = 0$ and $\overline{u} = \overline{d}$. Because the integral $\delta = \int(\overline{u} - \overline{d})dx$ is finite[4], this choice of $k$ allows the counting rule constraint (16) to be maintained as

$$\int_0^1 V dx = 3 + \delta \cdot \frac{3}{4} \cdot \frac{5 + 2\epsilon}{1 + \epsilon} = v(\epsilon, \delta). \tag{31}$$

If this constraint is released in a fit to the H1 data, a value of $\int V dx = 2.24 \pm 0.13(exp)$ is obtained instead of about 2.5 following from (31). The modified expression for the $A$ function in terms of quark distributions becomes

$$A = \frac{1}{4} \cdot \frac{1}{1+\epsilon}\Big[4\overline{u} - (u_v - 2d_v) - 5(\overline{u} - \overline{d}) + 2\epsilon(\overline{u} + \overline{d})\Big]. \tag{32}$$

For the naive assumptions $\epsilon = 0$ and $\overline{u} = \overline{d}$ this yields the approximate relation (17) and $A \simeq \overline{u}$ at low $x < 0.1$. In the analysis these generalised expressions are used for $V$, its integral and $A$.

[3] The evolution of $s + \overline{s}$ in DGLAP QCD is found to yield a linear dependence of $\epsilon$ on $\ln Q^2$ which is used to extrapolate the NuTeV result [84], obtained at $16\,\mathrm{GeV}^2$, to $Q^2 = Q_0^2$

[4] The most accurate measurement of $\int_0^1(\overline{u} - \overline{d})dx$ has been performed by the E866/NuSea Collaboration [65] which obtained a value of $-0.118 \pm 0.011$ at $\langle Q^2 \rangle = 54\,\mathrm{GeV}^2$

### A.2 Definition of minimisation procedure

The $\chi^2$ is computed as

$$\chi^2 = \sum_e \sum_d \frac{[\sigma_{rd,e} - \sigma_{rd,e}^{fit} \times (1 - \nu_e\delta_e - \sum_k s_e^k \cdot \delta_{d,e}^k)]^2}{[\sigma_{rd,e}]^2(\delta_{sta}^2 + \delta_{unc}^2)} + \sum_e \nu_e^2 + \sum_e \sum_k (s_e^k)^2. \tag{33}$$

The first two sums run over the data (index $d$) of the various experiments (index $e$). $\delta_e$ is the relative overall normalisation uncertainty and $\nu_e$ its change observed in the fit. $\delta_{d,e}^k$ denotes the relative correlated systematic error for a given error source $k$ and $s_e^k$ its observed change in the fit. $\delta_{sta}$ and $\delta_{unc}$ are the relative statistical and uncorrelated systematic errors, respectively, where the indices $d$ and $e$ have been omitted for clarity. For this measurement the relative correlated systematic errors $\delta_{d,e}^k$ are given in [46] and $\delta_{sta}$ and $\delta_{unc}$ are quoted in Tables 9-12.

### A.3 Parameterisations

As explained above, three parton distributions ($xg$, $V$ and $A$) are necessary to describe the proton structure function $F_2(x, Q^2)$ and its $Q^2$ evolution. The following general type of parameterisation is used

$$xq = a_q x^{b_q}(1 - x)^{c_q}[1 + d_q\sqrt{x} + e_q x + f_q x^2] \tag{34}$$

for $q = g$, $V$ and $A$. An attempt is made to describe these functions with the least number of parameters in the brackets of (34). All distributions are first calculated using recent parameterisations of parton distributions, by GRV98 [85], MRS99 [75] and CTEQ5 [86]. The resulting functions are fitted using the expressions of (34) in order to obtain initial information about how the new linear combinations of parton distributions $V$ and $A$ are possibly parameterised best. All global analysis distributions require the presence of $d_V$ and $e_V$ but allow $f_V$ to be set to zero. This defines the parameterisation of $V$ which mainly is a combination of valence quark distributions, see (30). For $xg$ and $A$, however, different parameter combinations are tested in a systematic way using fits to data.

The choice of a set of parameterisations is guided by the desire for a weak dependence of the $\chi^2$ function on the initial scale $Q_0^2$, and by the observed saturation of the $\chi^2$ when the number of parameters becomes too large. This is demonstrated in Fig. 24 for the fit to H1 data alone. The functions without a term $\propto \sqrt{x}$ in the $A$ distribution, see Table 8, yield a steady decrease of $\chi^2$ with $Q_0^2$.

Stability is observed for $Q_0^2 \geq 4$ GeV$^2$ for the other parameterisations. Three of them have a similar $\chi^2$. For the H1 fit the parameterisation CP3 is chosen. The functions CP4 and CP8 have one more parameter but only one unit of $\chi^2$ is gained which points to saturation of the parameter list. Although for CP7 a somewhat better $\chi^2$ is found, this parameterisation is not considered. It yields a too large gluon momentum as compared to the other fits

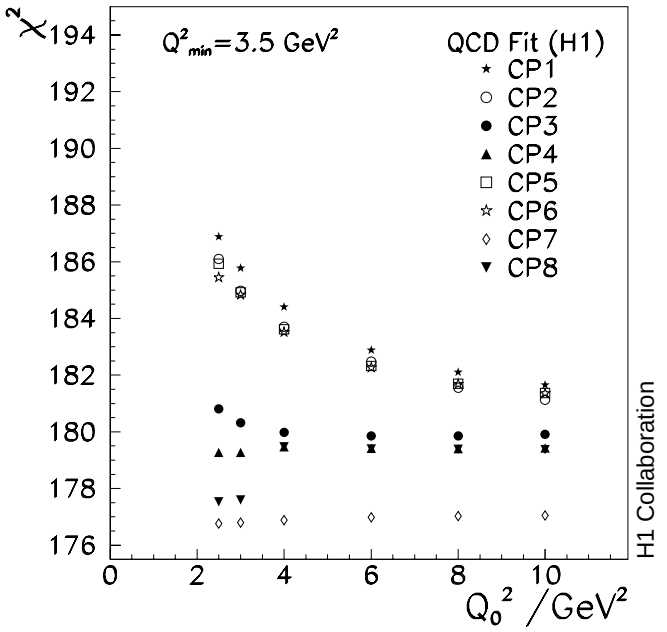

**Fig. 24.** Dependence of $\chi^2$ on the initial scale parameter $Q_0^2$ for different parameterisations of the parton distributions $xg$ and $A$ (Appendix A.3, Table 8) in the NLO QCD fit to the H1 data

**Table 8.** Types of parameterisations of the $xg$ and $A$ distributions at the initial scale $Q_0^2$

| type | gluon | A |
|---|---|---|
| CP1 | $1+ex$ | $1+ex$ |
| CP2 | $1+d\sqrt{x}+ex$ | $1+ex$ |
| CP3 | $1+ex$ | $1+d\sqrt{x}+ex$ |
| CP4 | $1+d\sqrt{x}+ex$ | $1+d\sqrt{x}+ex$ |
| CP5 | $1+ex$ | $1+ex+fx^2$ |
| CP6 | $1+d\sqrt{x}+ex$ | $1+ex+fx^2$ |
| CP7 | $1+ex$ | $1+d\sqrt{x}+ex+fx^2$ |
| CP8 | $1+d\sqrt{x}+ex$ | $1+d\sqrt{x}+ex+fx^2$ |

performed, including those using H1 and BCDMS data. These all agree for the gluon momentum fraction among each other and also with a previous analysis by the NMC collaboration [58]. In the CP7 fit to the H1 data apparently too many parameters are assigned to describe the quark distributions at large $x$ since this leads also to a distorted $V$ distribution.

The choice of parameterisation depends on the data set considered. In a similar study for the fit to H1 and BCDMS data, the parameterisation CP4 is chosen. Use of parameterisations with a high $x$ term $(1+\alpha x^{\beta})$, as introduced by the CTEQ collaboration [86], worsens the $\chi^2$ by eleven units and has thus not been considered further.

**Table 9.** The H1 measurement of the reduced deep-inelastic cross section with data taken in a dedicated low $Q^2$ trigger run in 1997. For $y < 0.6$ the structure function $F_2$ is extracted using the quoted values of $R$, derived from a QCD fit to the H1 cross section data. Fractional cross section errors are quoted in%. The total error ($\delta_{tot}$) is the quadratic sum of the uncorrelated ($\delta_{unc}$), the correlated ($\delta_{cor}$) and the experimental statistical error ($\delta_{sta}$)

| $Q^2/GeV^2$ | $x$ | $y$ | $\sigma_r$ | $R$ | $F_2$ | $\delta_{tot}$ | $\delta_{sta}$ | $\delta_{unc}$ | $\delta_{cor}$ |
|---|---|---|---|---|---|---|---|---|---|
| 1.5 | 0.0000320 | 0.518 | 0.786 | 0.346 | 0.832 | 5.5 | 1.3 | 3.5 | 4.0 |

**Table 10.** The H1 measurement of the reduced deep-inelastic cross section with data taken in a dedicated low $Q^2$ trigger run in 1997. For $y < 0.6$ the structure function $F_2$ is extracted using the quoted values of $R$, derived from a QCD fit to the H1 cross section data. Fractional cross section errors are quoted in %

**Table 15.** The H1 determination of the longitudinal structure function $F_L(x,Q^2)$. The errors are given in absolute, $\delta_{sta}$ representing the experimental statistics. The systematic errors consider all contributions from correlated and uncorrelated systematic error sources. $\delta_{met}$ is due to the uncertainties connected with the representation of $F_2$ in the derivative method, for $Q^2 < 10$ GeV$^2$, and in the QCD extrapolation method, for $Q^2 > 10$ GeV$^2$

| $Q^2/GeV^2$ | $x$ | $y$ | $F_L(x,Q^2)$ | $\delta_{sta}$ | $\delta_{sys}$ | $\delta_{met}$ | $\delta_{tot}$ |
